In *Edinburgh Circular* No. 38, Mr. Heath says that a second telegram from the same source states that the comet was again seen on the 10th, at 12h. 59·3m. M.T. at Kiel, its place being then R.A. 8h. 29m. 45·7s., N. Decl. 46° 59′ 29″; daily motion, + 34m. 48s. and − 1° 24′.

COMET FINLAY (1886 VII.).—A continuation of M. Schulhof's ephemeris for the ensuing week is as follows:—

12h. M.T. Paris.

1893		R.A. app.		Decl. app.
		h. m. s.		° ′ ″
July 13	...	3 59 23·84	...	+18 54 32·8
14	...	4 3 57·65	...	19 10 20·2
15	...	8 30·28	...	19 25 35·4
16	...	13 1·69	...	19 40 18·4
17	...	17 31·83	...	19 54 29·3
18	...	22 0·65	...	20 8 8·3
19	...	26 28·11	...	20 21 15·4
20	...	4 30 54·16	...	20 33 51·0

In the above ephemeris we have corrected the error made in the *Astronomische Nachrichten* (No. 3171), where the 16th is inadvertently printed 14th.

METEOR SHOWERS THIS MONTH.—In the list of the radiants of the principal meteor showers which Mr. Denning gives in the companion to the *Observatory* the following are visible this month, that occurring on the 28th being defined as "most brilliant":—

Date.		Radiant. α	δ		Meteors.
		°	°		
July 19	...	314	+48	...	Short, swift.
20	...	269	+49	...	Swift.
22	...	16	+31	...	Swift, streaks.
25	...	48	+43	...	Swift, streaks.
28	...	**339**	**−12**	...	Slow, long.
30	...	6	+35	...	Swift, streaks.

L'ASTRONOMIE FOR JULY.—The current number of this journal commences with an article by M. Tisserand on the inauguration of the statue of Arago, which was referred to in these pages last week. M. Deslandres briefly refers to some of his results as shown by the photographs taken by him at the late total solar eclipse, to which are added the observations of several other observers, and several illustrations of the instruments employed. M. Denning contributes three drawings of comet Holmes (made on November 9, 16, and 19 last), showing its change of shape from the circular to the pear-shaped form. Other articles of interest refer to meteorological statistics, atmospheric phenomena, earth tremblings, &c. In the notes some recent measures are given of the diameter of Mars, and of the snow caps, the former made by M. W. W. Campbell at the Lick Observatory, and the latter by M. Asaph Hall at the Washington Observatory.

HIMMEL UND ERDE FOR JULY.—In this number Dr. W. Luzi concludes his interesting article on the diamond, having covered the ground between the first observations made at Florence in 1694, and M. Moissan's recent researches. Dr. Wilhelm Meyer continues his chapters on the physical condition of the planet Mars after the evidence of eminent observers, while Herr Gingel gives us his fourth chapter on the mechanics of the heavens, dealing with the new researches by G. H. Darwin on the influence of tides on the movements and form-proportions of the heavenly bodies, embracing particularly the earth-moon system. Among the notes that on variable stars calls for attention.

MUSEUMS ASSOCIATION.[1]

II.

THESE are the principles of what may be called the New Museum idea as applied to national museums of natural history. It is a remarkable coincidence that since they were first enunciated, and during the time of their discussion, but before they had met with anything like universal acceptance, the four first nations of Europe almost simultaneously erected in their respective capitals—London, Paris, Vienna, and Berlin—entirely new buildings on a costly, even palatial scale, to receive the natural history collections, which in each case had quite outgrown their previous insufficient accommodation. In the construction of neither of these four edifices can the guardians of the public purse be accused of want of liberality. Each building is a monument in itself of the appreciation of the government of the country of the value and interest of the natural history sciences. So far this is most satisfactory. Now that each is more or less completed, at all events for the present, and its contents in a fair way towards a permanent arrangement, it may not be without interest on the present occasion to give some comparative account of their salient features, especially with a view to ascertain whether and to what extent their construction and arrangement have complied with the requirements of the modern idea of such institutions.

It may seem ungrateful to those who have so liberally responded to the urgent representations of men of science by providing the means of erecting these splendid buildings, to suggest that if they had all been delayed for a few years the result might have been more satisfactory. The effects of having been erected in what may be called a transitional period of museum ideas is more or less evident in all, and all show traces of compromise, or rather adaptation to new ideas of structures avowedly designed for old ones. In none, perhaps, is this more strikingly shown than in our own, built, unfortunately, before any of the others, and so without the advantages of the experience that might have been gained from their successes or their shortcomings. Though a building of acknowledged architectural beauty, and with some excellent features, it cannot be taken structurally as a model museum, when the test of adaptation to the purpose to which it is devoted is rigidly applied. But to speak of its defects is an ungracious and uncongenial task for me. If it were not taking me too far away from my present subject I would rather speak of the admirable manner in which the staff are endeavouring to carry out the new idea under somewhat disadvantageous circumstances.

The new zoological museum in the Jardin des Plantes at Paris is a glorification of the old idea pure and simple. It consists of one huge hall, with galleries and some annexes, in which every specimen is intended to be exhibited, more or less imperfectly, on alternate periods to students and to the general public. The building and cases are very handsome in style, and there are endless rows of specimens of all kinds neatly mounted in a uniform manner. There are no storerooms, no laboratories, no workrooms connected with the building. These are all in

[1] Continued from p. 236.

other more or less distant parts of the establishment, separated from it in most cases by the whole breadth of the garden. Of course this can only be looked upon as a temporary condition of affairs. Fortunately there is still room on the site of the old museum behind the new building, and if this is utilised by erecting upon it a commodious set of workrooms, laboratories, rooms for reserve collections and administrative offices directly in connection with each other and with the main building, which might then be emptied of a considerable portion of its contents, an extremely good working museum may be evolved. But if this space, as I believe was the original design, is used for the further extension of the already over large public galleries, the opportunity will be lost.

The new museums at Vienna, the one for natural history, the other for art, placed one on each side of a handsome public garden in one of the most important quarters of the city, exactly alike in size and architectural features, are elegant buildings, and present many excellent features of construction. The natural history museum, which was alone finished when I visited Vienna three years ago, is a quadrilateral structure with a central court, and consists of three stories and a basement. Each story is divided into a number of moderately-sized rooms, opening one into another, so that by passing along in the same direction, the visitor can make an inspection in systematic order of all the collections arranged in each story, returning to the point from whence he started; or, if need be, breaking off at the middle where a passage of communication runs across the central court. An admirable feature in the design of this museum, is that the public galleries of each story, lighted by windows from the outside of the building, have on their inner side other rooms communicating with them, and lighted from the court within, which are devoted to the private studies of the curators and to the reserve collections belonging to the same series as the exhibited collections in the public galleries with which they are in connection. Thus the public collections, the reserve collections, and the officers in charge are are in each section of the museum brought into close relation—a most advantageous arrangement—and one greatly facilitating the new museum idea. The only drawback is that these rooms, occupying the inner side of the quadrangular range of galleries, are necessarily small, and as the collections grow, will be found insufficient for the purpose. This has, in fact, already proved to be the case in several departments, and a remedy has been found by devoting the whole upper story of the building to the reserve collections of insects, shells, and plants, and the working library of the institution, an arrangement which gives excellent accommodation for these important departments, at all events for the present. Another great future difficulty will arise, owing to the building being externally architecturally complete and visible on all four sides from the public grounds in which it stands; it therefore admits of no extension, and the public galleries already contain as many specimens as can possibly be placed in them with any advantage. These are in most sections, especially the invertebrata, displayed in an extremely tasteful and instructive manner, but the series is by no means over large for a national museum. The limitation of space is partly due to the somewhat singular division which has been made between the art and the natural history collections. Instead of taking the dividing line adopted at the British Museum between specimens in a state of nature, and those fashioned by man's hand, the pictures, the splendid collection of European mediæval armour, the classical and Egyptian antiquities are treated as works of art; but the so-called ethnological collection, containing the specimens of Mexican, Peruvian, Japanese, Chinese, Polynesian, African, and prehistoric European art, are placed in the Natural History Museum, taking up a large portion of the space, which the curators of the zoological, mineralogical, and geological departments hoped to have had at their disposal for the display of their specimens. Whether room could be found for them in the Art Museum or not I cannot say; but certainly their actual position is incongruous, and it is difficult to understand why a Peruvian mummy should find its place in a building professedly devoted to natural history, while the preserved remains of an ancient Egyptian are treated as works of art.

Before leaving Vienna I should like to refer to the splendid specimens of taxidermy by the artist Hodek, the choicest examples of whose work are contained in a special collection, occupying a small separate room, consisting of sporting trophies of the late Crown Prince Rudolph. Otherwise the general level of the specimens in the galleries is in no wise remarkable. The birds have the advantage of being mounted, not upon turned wooden stands of uniform pattern as in Paris, but upon pieces of natural tree branches, fixed in square or oblong oak stands. The exhibited specimens of vertebrate zoology include skeletons, but no other anatomical preparations, of which there is a distinct collection in the University Museum. The exhibited fishes and reptiles are exceedingly well preserved and mounted in spirit. In the Mollusca, Articulata, Echinoderms and Corals great care has been taken in setting the specimens off to advantage by selecting appropriate colours for backgrounds. Specimens in spirit are interspersed in their proper places. All have printed labels. The cases in which they are displayed are of oak, and of very handsome and even ornamental construction.

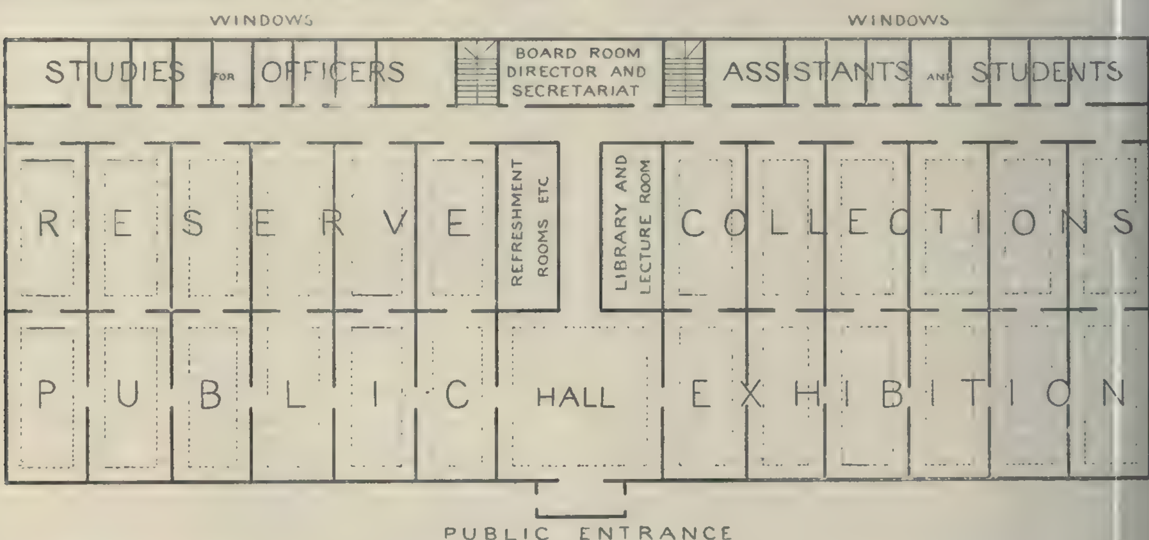
The arrangement of all these collections displays a most intelligent appreciation of the needs of the ordinary visitor. Thus in the room appropriated for the exhibition of insects there are three distinct series, a general systematic series, a morphological series, and a very fine special collection of the insects of the neighbourhood of Vienna. The other rooms are arranged more or less on similar principles The main collection of insects, is, as I have mentioned before, entirely apart in rooms very well adapted to the purpose in the upper floor of the building, and kept as usual in drawers in cabinets.

The zoological portion of the new museum for "Naturkunde," in Berlin, situated in the Invaliden Strasse, is a remarkable illustration of the complete revolution of ideas on museum arrangement, which took place between its commencement and its completion. The building, entirely designed upon the old system, came empty into the hands of the present director, who has arranged the contents absolutely upon the new method. It consists of a fine glass covered hall, and three stories of galleries, all originally intended for a uniform exhibition of all the various groups of specimens which had accumulated in the crowded rooms of the old museum in the University. When Dr. Möbius succeeded to the directorate he conceived the bold plan of limiting the public exhibition to the ground floor, and devoting the two upper stories entirely to the reserve or working collections. This was a step which required some courage to take, especially as the two great staircases, which are the principal ornamental architectural features of the building, have by it become practically useless. Except, of course, for certain inconveniences always resulting from adaptation of a building to purposes not originally contemplated, especially local disjunction of different series of the same groups, the result has been eminently satisfactory, and if the arrangement is completed upon the lines laid down by the Director, as explained to me on my last visit, this will be the most practical and conveniently arranged museum of natural history at present existing. As much attention appears to be bestowed upon making the exhibited portion attractive and instructive, as on making the reserve collections complete and accessible to workers. In the former, the characteristics of the native fauna were being specially developed. For instance, the fish collection (of which the individual specimens are beautifully displayed, fastened on to glass plates in flat-sided bottles) consists of a general representative systematic series, and three special faunistic collections, one of the German fresh-water fishes, one of the north and east sea fishes, and one of the Mediterranean fishes. One room is devoted to German mammals and birds, and the recently added specimens show indications of an improvement in taxidermy which would have been impossible in the old days of wholesale bird-stuffing. Excellently prepared anatomical specimens, diagrams, explanatory labels, and maps showing geographical distribution, are abundantly introduced among the dried specimens of which such collections are usually composed, and a commencement has been made of illustrations of habits and natural surroundings. On the other hand, in marked contrast to Vienna, everything in the way of architecture and furniture and fittings is severely plain and practical, and a uniform drab colour is the pervading background of all kinds of specimens. All danger from fire seems to have been most carefully guarded against. The floors are of artificial stone, the cases, and even the shelving, are constructed of glass and iron. Wood is almost entirely excluded, both in the structure and fittings. The ground floor, as I have said, is entirely devoted to the public exhibition, the first story to the reserve collection of vertebrates, and the upper story to the invertebrates; and the basement contains commodious rooms for unpacking, mounting, preparing skeletons, &c. The construction of the building allows of considerable extension backwards, whenever more space will be needed, at small cost and with little interference with existing arrangements. I should also mention that the zoological department of the University, with its admirably appointed laboratories and lecture-rooms, and excellent working collection for teaching purposes, is in immediate contact with the museum, and the two institutions, though under different direction, are thus brought into harmonious cooperation.

Any one who wishes to compare and contrast the two systems upon which a national zoological museum may be arranged cannot do better than visit Paris and Berlin at the present time. He will see excellent illustrations of the best of both.

Of the museums of the United States of America much may be expected. They are starting up in all directions untrammelled by the restrictions and traditions which envelope so many of our old institutions at home, and many admirable essays on museum work have reached us from the other side of the Atlantic, from which it appears that the new idea has taken firm root there. In Mr. Brown Goode's lecture on "The Museums of the Future" (Report of the National Museum, 1888–89) it is said "In the National Museum in Washington the collections are divided into two great classes. The exhibition series, which constitutes the educational portion of the museum and is exposed to public view with all possible accessions for public entertainment and instruction, and the study series, which is kept in scientific laboratories and is scarcely examined except

In the first place, I have endeavoured to work out in detail, in its application to natural history, that most original and theoretically perfect plan for a museum of exhibited objects in which there are two main lines of interest running in different directions and intersecting each other, which we owe to the ingenuity of General Pitt-Rivers. This was explained in his address as President of the Anthropological Section of the British Association at Bath in 1888, and again in a lecture given about two years ago before the Society of Arts. Upon this plan the museum building would consist of a series of galleries in the form of circles, one within the other, and communicating at frequent intervals. Each circle would represent an epoch in the world's history, commencing in the centre and finishing at the outermost, which would be that in which we are now living. The history of each natural group would be traced in radiating lines, and so by passing from the centre to the circumference, its condition of development in each period of the world's history could be studied. If, on the other hand, the subject for investigation should be the general fauna or flora of any particular epoch, it would be found in natural association by confining the attention to the circle representing that period. By such an arrangement that most desirable object, the union of palæontology with the zoology and botany of existing forms in one natural scheme, could be perfectly carried out, as both the structural and the geological relations of each would be preserved, as indicated by its position in the museum. Such a



by professional investigators. In every properly constructed museum the collections must from the very beginning divide themselves into these two classes, and in planning for its administration, provision should be made not only for the exhibition of objects in glass cases, but for the preservation of large collections not available for exhibition to be used for the studies of a very limited number of specialists."

The museum of comparative zoology at Harvard, founded by the late Louis Agassiz and now ably administered and extended by his son, Alexander Agassiz, is a conspicuous example of the same method of construction and arrangement. But as I can say nothing of these from personal knowledge, I am obliged to leave out any further reference to them on the present occasion.

From what has just been said it will be gathered that in Europe at least an ideal natural history museum, perfect in original design, as well as in execution, does not exist at present. We have indeed hardly yet come to an agreement as to the principles upon which such a building should be constructed. But as there are countries which have still their national museums in the future, and as those already built are susceptible of modifications, when the right direction has been determined on I should be glad to take this opportunity of putting on record what appears to me, after long reflection on the subject, the main considerations which should not be lost sight of in such an undertaking.

building would undoubtedly offer difficulties in practical construction, but even if these could be got over, our extremely imperfect knowledge of the past history of animal and plant life would make its arrangement with all the gaps and irregularities that would become evident, so unsatisfactory, that I can scarcely hope to see it adopted in the near future.

I have therefore brought before you a humbler plan, but one which, I think, will be found to embody the practical principles necessary in a working museum of almost any description, large or small.

The fundamental idea of this plan is that the whole of the building should be divided by lines intersecting at right angles, like the warp and the woof of a piece of canvas.

The lines running in one direction divide the different natural sections of which the collection is composed, and which it is convenient to keep apart; the lines crossing these separate the portions of the collection according to the method of treatment or conservation. Thus, the exhibited part of the whole collection will come together in a series of rooms, occupying naturally the front of the building. The reserve collections will occupy another, or the middle, section, and beyond these will be the working rooms, studies, and administrative offices, all in relation to each other, as well as to the particular part of the collection to which they belong. A glance at the plan will show at once the great convenience of such a system, both for the public, and still more for those who work in the museum.

This plan, of course, contemplates a one-storied, top-lighted building as far as the main rooms are concerned, although the workrooms and studies will be in two or more stories. The main rooms should all have a good substantial gallery running round them, by means of which their wall space is doubled. There is no question whatever that an evenly-diffused top light is far the best for exhibition rooms. Windows not only occupy the valuable wall-space, but give all kinds of uncomfortable cross lights, interspersed with dark intervals. On the other hand, for doing any kind of delicate work, a good north light from a window, as provided in the plan, is the most suitable. The convenience of having all the studies in relation with each other, and with the central administrative offices, while each one is also in close contiguity with the section of the collection to which it belongs, will, I am sure, be appreciated by all who are acquainted with the capriciously scattered position of such rooms in most large museums, notably in our own. Among other advantages would be the very great one that when the daily hour of closing the main building arrives, the officers need no longer, as at present, be interrupted in whatever piece of work they may have at hand, and turned out of the building, but as arrangements could easily be made for a separate exit, they could continue their labours as long and as late as they find it convenient to do so, without any fear for the safety of the general collections.

It will be observed that provision is made for a central hall, which is always a good architectural feature at the entrance of a building, and which in a museum is certainly useful in providing for the exhibition of objects of general interest not strictly coming under any of the divisions of the subject in the galleries, or possibly for specimens too large to be conveniently exhibited elsewhere. There is also provision in the central part of the building for the refreshment-rooms, and also for the library and a lecture room; the first being an essential, and the latter a very useful adjunct to any collection intended for popular instruction, even if no strictly systematic teaching should be part of its programme.

I may point out, lastly, as a great advantage of this plan, that it can be, if space is reserved or obtainable, indefinitely extended on both sides on exactly the same system without in any way interfering with the existing arrangements, a new section, containing exhibition and reserve galleries and studies can be added as required at either end, either for the reception of new departments, or for the expansion of the old ones. With a view to the latter it is most important that the fittings should be as little as possible of the nature of fixtures, but should all be so constructed as to be readily removable and interchangeable. This is a point I would strongly impress upon all who are concerned in fitting up museums either large or small.

The modifications of this plan to adapt it to the requirements of a municipal, school, or even village museum will consist mainly in altering the relative proportion of the two sections of the collection. The majority of museums in country localities require little, if anything, beyond the exhibition series. In this the primary arrangement to be aimed at is first, absolutely to separate the archæological, historic, and art portions of the collection from the natural history, if, as will generally be the case, both are to be represented in the museum. If possible they should be in distinct rooms. The second point is to divide each branch into two sections: 1, a strictly limited general or type collection, arranged upon a purely educational plan; 2, a local collection, consisting only of objects found within a certain well-defined radius around the museum, which should be as exhaustive as possible. Nothing else should be attempted, and therefore reserve collections are unnecessary. Even the insects and dried plants can be exhibited on some such plans as those adopted for the Walsingham collection of Lepidoptera in the Zoological Department, or the collection of British plants in the Botanical Department in our Natural History Museum.

I have elsewhere indicated my views as to the objects most suitable for, and the best arrangement of them in, school museums,[1] so I need say nothing further on the subject now. Indeed I fear I have exhausted your patience, so I will conclude by expressing an earnest hope that this meeting may prove a stimulus to all of us to continue heartily and thoroughly at our work, which I need not say is the only way to ensure that general recognition of it which we all so much desire.

[1] NATURE, vol. xli. p. 177, December 26, 1889.

At the close of the address a vote of thanks was moved by Sir James Paget and seconded by Sir Henry H. Howorth. The meeting was largely attended by delegates from various provincial museums, as well as by representatives of a number of museums and scientific societies in the metropolis. Among those present were Sir Joseph Fayrer, Dr. Jonathan Hutchinson, General Festing, Lady Flower, Dr. Günther, Dr. Sclater, Dr. Henry Woodward, Mr. L. Fletcher, Mr. and Mrs. Cuthbert Peek, Mr. W. Topley, Mr. E. F. Newton, Prof. Jeffrey Bell, Mr. Osbert Salvin, Mr. F. W. Rudler, and others. The following museums were represented:—

Bootle, Bolton, Brighton, Cardiff, Chester, Dublin, Glasgow, Maidstone, Manchester, Nottingham, Parkes Museum, Saffron Walden, Sheffield, Southampton, Stockport, Sunderland, Warrington, and York.

At the conclusion of the proceedings Sir William and Lady Flower held a reception in the library of the Zoological Society.

July 4, 5, and 7 were occupied by the business of the Association. As on previous occasions, papers were read and discussed and general business transacted during the mornings; while the afternoons were devoted to the inspection of museums. The Association owes a debt of gratitude to several societies and individuals for courtesy and hospitality. The convenient rooms of the Zoological Society, at 3 Hanover Square, were kindly placed at the disposal of the Association by the Council of the Society, and the Anthropological Society kindly gave the use of its library. The Council of the Royal College of Surgeons invited the members of the Association to the conversazione held at the Museum on July 5. The Royal Society and the Geological Society allowed members of the Association the privilege of inspecting their collections, and the officers of the British Museum (both at Bloomsbury and at Cromwell Road), and of the Museum of Practical Geology, conducted the members over the departments under their charge. Dr. and Mrs. Woodward held a reception at 129, Beaufort Street on July 6, and Mr. Jonathan Hutchinson entertained a party at Haslemere on July 8, and exhibited his educational museum to his guests.

THE DISTRIBUTION OF MARINE FLORAS.

IN *Phycological Memoirs*, Part II., May 1893, Mr. George Murray gives a comparative table, showing the marine floras of the warm Atlantic, Indian Ocean, and the Cape of Good Hope.

Preceding the comparison, he says:—"In delimiting the above regions I have been guided by what may fairly be taken to be their natural boundaries. The warm Atlantic is the tropical Atlantic, with a slight northward extension, to include Florida, the Bahamas, and Bermuda in the track of the Gulf Stream, and also Madeira and the Canary Islands, washed by that branch of the same stream which trends off backward to the south, the north equatorial current. I have not included the Azores, since they are not sufficiently under this influence, and their marine flora, so far as we know it, appears to be more akin to that of the north temperate Atlantic. On its southern boundary on the African coast the Cape region is permitted to come slightly within the tropics, so far as Wallfisch Bay, on account of this coast being swept by a cold current from the south, bringing with it up to this point at all events such temperate forms as *Laminaria*, recently recorded from that place. The Indian Ocean similarly is the tropical Indian Ocean, but including the whole of the Red Sea, and extending to the south slightly outside the tropics down the coast of Africa, and including the whole of Madagascar. I am justified in this by the course of the warm Mozambique current. I do not include on the east Sumatra, which appears to belong to another region, though I have included a few forms from the Andaman Islands and Mergui. The Cape of Good Hope region has already been indirectly described, and, as has been said, extends for the reasons given, slightly into the tropics on the west coast, and recedes slightly from that boundary on the east coast."

The table shows that the warm Atlantic has the largest recorded flora, viz. 859 species in 162 genera. I may explain that, out of this total, no less than 788 species in 150 genera occur in the West India region, and that the rest of the warm Atlantic furnishes only 71 species in 12 genera not occurring in the West Indies out of a much smaller total flora. Allowing for the undoubted fact that a large number of West Indian species are bad species, there still remains a large balance in its favour. It has been better examined than any other part of the warm Atlantic, but still we may attribute this preponderance mostly to the favourable natural conditions, principally the coral formation of large portions of its island shores. On the coast of Africa there is not only no coral, but league after league of muddy shore, making a marine desert so far as Algæ are concerned. The Indian Ocean comes next, with 514 species in 139 genera. It possesses an enormous coast line, to a considerable extent favourable to the growth of Algæ (though including long desert stretches); but the bulk of the records are from Ceylon, Mauritius, and the Red Sea, while a very large proportion of the region is unexamined. As in the West Indies, there is also here a considerable proportion of bad species, principally *Sargassa*, from the Red Sea. From the Cape we have 429 species in 141 genera. This remarkable total, from so short a coast line, is obtained from Miss Barton's list in the *Journal of Botany*, 1893. The flora previously recorded in books amounted only to 242 species in 99 genera, and this addition to its flora has resulted from her examination of the British Museum Herbarium, and her naming of the admirable collection made by Mr. Boodle, and also those made by Mr. Scott Elliot and Mr. Tyson. The most noteworthy observation on these aggregates is the proportion of species to genera. In the warm Atlantic the genus averages well over 5 species; in the Indian Ocean the proportion is nearer 4 than 3 species to the genus; while at the Cape it is almost exactly 3. This is instructive when we remember, as I have elsewhere pointed out (Trans. Biol. Soc. Liverpool, vol. v. p. 177), that while the Arctic Algæ average slightly more than 2 species only to the genus, the West Indies and Australia average rather more than 5 and less than 5 respectively. I estimate that the north temperate Atlantic yields an average of about 4½ species to the genus, and the difference between this and 3 species per genus found at the Cape is to be attributed primarily to the short coast line of the Cape, and in a less degree to its Algæ being less known. The calculation of such averages and proportions appears to me to be justified only when applied to the whole flora, and becomes more dangerous and apt to mislead when applied to portions of it, since particular groups in all the floras have been subjected to unequal treatment by collectors and describers, and we may perhaps trust to these personal errors neutralising each other when the complete totals are compared.

The warm Atlantic and Cape have 85 genera and 114 species in common, while the Indian Ocean and Cape have 86 genera and 89 species in common. That the number of genera in common should be so nearly exactly similar is interesting, and to discover whether they are the same genera in many cases it is only necessary to turn to the last table, where the Algæ common to all three regions are given to find that 72 genera are common to all three. Some years ago I hazarded the speculation that, while the genera of the tropical Atlantic and those of the Indian Ocean were largely the same, the species were, in a high proportion, different ("Catalogue of Marine Algæ of the West Indian Region"). We can now see that they have no less than 103 genera in common out of a total of 139 occurring in the Indian Ocean and 162 in the warm Atlantic. They have certainly more species in common, viz. 173, but these must be considered relatively to the two totals of 514 in the Indian Ocean and 859 in the warm Atlantic, when my expectation will appear to be fairly borne out. Nevertheless, I confess to having anticipated an even greater diversity of species. That the absolute number of genera occurring at the Cape should be by two greater than those of the Indian Ocean completely puzzles me. I cannot fully account for it on any theory. While the number of species in common between any two of the floras is greater than the number of genera (though in one case only three more), the number of species, as might be expected, in common to all three—viz. 59—is less than the genera—viz. 72. Again I should have expected to find relatively fewer species in common.

When one comes to analyse these totals, the process must be carried on in a more guarded fashion. One expects, as shown above, to find fewer species to the genus at the Cape than in the tropical floras, but one hardly expects to find that the genera of *Florideæ* at the Cape are by five more numerous than in the warm Atlantic, and by 15 more than in the Indian Ocean. There are no less than 95 genera of *Florideæ* at the Cape, with 295 species, while the 90 of the warm Atlantic contain nearly 200 more species! Matters are much the same in the case of the *Phæophyceæ*, and we have come to the *Chlorophyceæ* to redress the balance in the case of the warm Atlantic. They just fail to bring it level in the case of the Indian Ocean. It has been remarked above that the genera which the two tropical floras have in common with the Cape are almost identical in number. The analysis shows that the figures are very steady, viz. 58 each of *Florideæ*, 14 and 15 of *Phæophyceæ*, 11 each of *Chlorophyceæ*, and two each of *Protophyceæ*. The table shows the tropical character of such a group as the *Siphoneæ* very markedly. There are 99 species in 23 genera in the warm Atlantic, 72 species in 16 genera in the Indian Ocean, and only 20 species in 7 genera at the Cape. It is interesting to observe that the whole of the 16 genera of *Siphoneæ* in the Indian Ocean are represented in the warm Atlantic. It has no peculiar generic type of its own in this tropical group. While the genera of this tropical order are thus practically identical, the species are in a very high proportion different. Only 29 are possessed in common out of the two totals of 99 and 72. In the comparison of the two tropical floras there is the coincidence that the genera and species of *Siphoneæ* agree exactly in numbers, viz. 16 and 29, with the total of all the *Phæophyceæ*—a thing without significance, however.

The interest that is attached to the above comparison is mainly this. We have here two tropical marine floras cut off from each other by a permanent continental area, and communicating only *viâ* the Cape. That these floras have been periodically mingled at the epochs of warmer climate at the Cape seems a reasonable conclusion with regard to a group of such antiquity as the Algæ, and the proportions of species in common and genera in common between the different regions, and among all three may have a significance in this respect to students of distribution (cf. the totals of *Siphoneæ*, a peculiarly tropical order). I have elsewhere (Trans. Biol. Soc. Liverpool, vol. v. p. 178) commented on the fact that, "while in the Arctic and Australian regions the *Phæophyceæ* far outnumber the *Chlorophyceæ*, in the tropical West Indian flora the proportion is very markedly reversed, and the green Algæ outnumber the olive-brown. One is tempted to put this down to the strong illumination of the tropical sea, but another reason is to be found in the fact that a number of the Antilles richest as regards Algæ are subject to irruptions of fresh and brackish water from the Orinoco floods—a condition that would operate in the same direction." We can now check this speculation by a comparison with the figures for the Indian Ocean, mainly derived from such localities as the Red Sea, Ceylon, Mauritius, &c., in no case affected by the question of fresh-water floods. The figures for the Indian Ocean are very nearly the same for both groups—24 genera and 117 species of *Phæophyceæ*, and 26 genera and 121 species of *Chlorophyceæ*—thus showing indirectly that the irruptions of fresh water are, in all probability, potent in the case of the West Indian Algæ. One is much struck by the strength of illumination of the bottom in a shallow coral sea, but the filtering action by sea water of the rays of light, and the interception first of those rays that are most efficient in the work of assimilation—conditions modifying the pigments of Algæ—are the same in all seas.[1] The practically tideless character of the Antilles would also make for a preponderance of green over olive-brown forms.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE Bristol Medical School, which was established early in this century, has, since the establishment of University College, Bristol, about seventeen years ago, been affiliated to it, but remained under the direction of a separate governing body. Within the last few months the two institutions have been amalgamated and placed under one Council, and the Medical School now constitutes the faculty of medicine in the College.

THE Council of University College, Bristol, have raised to the status of Professor, in the Faculty of Arts and Science, Mr. F. R. Barrell, Lecturer in Mathematics, and Mr. A. P. Chattock, Lecturer in Physics, and have also appointed Dr. Edward Fawcett, late Senior Demonstrator of Anatomy in the Yorkshire College, Leeds, to the Professorship of Anatomy in the Faculty of Medicine.

[1] Recent research on other pigments by Prof. Marshall Ward makes it appear to me more probable that, in the case of the marine Algæ, the pigments are rather shields against the excess of blue rays than adaptations to heighten the susceptibility of chlorophyll to the diminished supply of the others.

HER Majesty's Commissioners for the exhibition of 1851 have made the following appointments to science research scholarships for the year 1893, on the recommendation of the authorities of the respective Universities and colleges. The scholarships are of the value of £150 a year, and are tenable for two years (subject to a satisfactory report at the end of the first year), in any University at home or abroad, or in some other institution to be approved of by the Commissioners. The scholars are to devote themselves exclusively to study and research in some branch of science, the extension of which is important to the industries of the country. The list of scholars and of the nominating institutions is as follows:—Herbert William Bolam, University of Edinburgh; George Edwin Allan, University of Glasgow; James Wallace Walker; University of St. Andrews; Arthur Lapworth, Mason College, Birmingham; John Ellis Myers, Yorkshire College, Leeds; Arthur Walsh Titherley, University College, Liverpool; Edward Chester Cyril Baley, University College, London; John Cannell Cain, Owens College, Manchester; Ella Mary Bryant, Durham College of Science, Newcastle-on-Tyne; James Darnell Granger, University College, Nottingham; Mary O'Brien, University College of Wales, Aberystwyth; Frederick George Donnan, Queen's College, Belfast; James Alexander M'Phail, M'Gill University, Montreal; Norman Ross Carmichael, Queen's University, Kingston, Canada; William Henry Ledger, University of Sydney.

MISS MARIA M. OGILVIE, daughter of Dr. Ogilvie, of Gordon's College, Aberdeen, has passed the final examination for the degree of Doctor of Sciences of London University. The subject of her thesis was the "Geology of the Wingen and St. Cassian Strata in Southern Tyrol," published in the *Quarterly Journal* of the Geological Society for February.

THE electors to the Savilian Professorship of Astronomy will proceed to the appointment of a successor to the late Prof. Pritchard, in the couse of the ensuing Michaelmas Term. The duties of the Professor are defined by the following provisions of the statutes:—The Savilian Professor of Astronomy shall lecture and give instruction on theoretical and practical Astronomy. "Ne alia quapiam professione eodem tempore fungatur professor; nec munus observatoris Radcliviani, nec officium prælectoris alicujus in quovis collegio publice legentis cum munere suo conjungat." The Professor shall reside within the University during six months, at least, in each academical year, between the first day of September and the ensuing first day of July. He shall lecture in two at least of the three University terms. His lectures shall extend over a period not less in any term than six weeks, and not less in the whole than fourteen weeks, and he shall lecture twice at least in each week. The University Observatory shall be open for eight weeks in each term, and at such other times and for such hours as the University may by statute determine. The Savilian Professor of Astronomy shall have the charge of the University Observatory, and shall undertake the personal and regular supervision of the same, and of the several demonstrators and other assistants employed therein, and shall be responsible for all the work carried on there. The emoluments of the Professorship as determined by statute are as follows:—He shall be entitled to the emoluments now assigned to the Professorship and derived from the benefaction of Sir Henry Savile, Knight, or from the University Chest; and shall receive in addition the emoluments appropriated to the Professorship by the statutes of New College. The total amount of all these emoluments is at present £850 a year. Applications, together with such papers as the candidate may desire to submit to the electors, must be sent to the Registrar of the University, Clarendon Building, Oxford, on or before October 31, 1893.

ARRANGEMENTS have been completed for the seventh session of the Edinburgh Summer Meeting, which begins on July 31, and lasts throughout August. Among the better known lecturers are:—M. Edmond Demolins, M. Paul Desjardins, Prof. Patrick Geddes (who will treat of contemporary social evolution), Prof. Lloyd Morgan (giving a course of comparative psychology—perhaps the first of its kind in Britain) and Mr. Arthur Thomson, discussing bionomics and evolution. A course on the history and principles of the sciences will be conducted by Prof. Cargill Knott, Dr. Charles Douglas, and others. A characteristic feature will be the series of studies entitled "A Regional Survey of Edinburgh and Neighbourhood." Among other subjects are Physiology, Modern History, Education and Elocution, and there will be practical classes in Botany, Zoology, and Geology. Work will be continued in the seminars and the studios, and a new departure is the course of Sloyd. While the student is obviously invited to serious work, a pleasant relief is promised in the shape of excursions.

THE New York *Nation* says that on June 14, at the University of Virginia, for the first time in its history, a certificate of attainment qualifying for graduation (in the School of Pure Mathematics) was given to a woman, Miss Caroline Preston Davis. Miss Davis, while excluded from the lectures, had taken successfully the same examinations on the same day with the male students, but "in a separate room"; and, at the request of the Chairman of the Faculty, the graduating class in a body handed the certificate to her.

SOME years ago (writes the Allahbad *Pioneer Mail*), the Senate, or the Syndicate, of the University of Madras promulgated a rule that any examiner who failed to send in his marks by a certain fixed date would be fined 20 rupees for each day's delay. The Syndicate, however, refrained from acting on this remarkable rule until this year, when its sense of humour was too strong for it, and it determined to carry its little joke to its conclusion. A number of examiners were accordingly fined. One gentleman earned a fee of 210 rupees, but he was fined 200 rupees, and received a pay bill for 10 rupees. Entering into the spirit of the thing, he returned this amount to the Registrar as a present to the University, and possibly it will be invested, and the proceeds devoted to the purchase of an infinitesimal medal, as the custom is. But, seriously, it is most regrettable that the Syndicate should deliberately degrade its examiners in this way. Surely it is possible to find a sufficient number of gentlemen who can be trusted to do their work with such promptness as is compatible with fairness to the candidate, and more than this the Senate cannot desire. If an examiner is guilty of great delay, the remedy is simple—do not appoint him again. But to treat an examiner like a careless domestic is as insulting to him as it is undignified on the part of the University.

MR. F. W. GAMBLE, B.Sc. (Victoria), formerly Bishop Berkeley Research Fellow in Zoology, has been appointed to the post of Assistant Lecturer and Demonstrator in Zoology in the Owens College, Manchester

BISHOP BERKELEY Research Fellowships has been awarded by the council as follows:—H. B. Pollard, M.A. (Oxon.), in Zoology; Albert Griffiths, M.Sc. (Vict.), in Physics; J. A. Harker, D.Sc. (Tübingen), in Physics; Bevan Lean, B.A., B.Sc. (Lond.), in Chemistry; and a Fellowship has been renewed to Stanley Dunkerley, M.Sc. (Vict.), in Engineering.

SCIENTIFIC SERIALS.

Bulletin of the New York Mathematical Society, Vol. ii. No. 9, June, 1893.—The mechanics of the earth's atmosphere is a collection of translations by Cleveland Abbe (published by the Smithsonian Institution, 1891, 324 pp. 8vo). An account of it is furnished by R. S. Woodward (pp. 199–203). The volume contains twenty papers, all but two of which were published originally in the German language. The opening paper is by Hagen (1874), then follows the classic memoir by Helmholtz (1858), with five others by the same author. Then comes the extension of one of the last cited papers by Kirchhoff (1869); we then have five memoirs by Oberbeck, a paper by Hertz (1884), three papers by Bezold (1888–1889), a paper by Lord Rayleigh (1890, on the vibration of the atmosphere), and papers by Margules (1890) and Ferrel (1890). It will be readily inferred from this outline that Mr. Abbe has performed a work of prime importance to mathematical meteorologists. Dr. T. S. Fiske (pp. 204–211) also gives an outline sketch of mathematical investigations in the theory of values and prices, by Dr. I. Fisher (reprinted from the Transactions of the Connecticut Academy, July, 1892). The number closes with a few brief notes and a list of recent publications.

Wiedemann's Annalen der Physik und Chemie, No. 6.—On the determination of electrical resistances by means of alternating currents, by F. Kohlrausch. This is a minute study of the errors involved in measuring liquid resistances with alternate currents and the telephone. For potassium chloride solution between clean platinum electrodes, the error by which the resistance of the liquid was found too great remained below 1 per cent. so long as the product of the resistance in ohms and the surface of the electrode in sq. cm. did not fall below 250. In cases of high resistance, say 100,000 ohms, where MM.

Bouty and Foussereau failed altogether to obtain consistent results, these may be secured by using certain precautions, such as placing the induction coil at a sufficient distance (1 m. at least) from the bridge, directing its axis perpendicular to that of the rheostat, and placing the telephone perpendicular to the lines of force of the induction coil. In the case of water and very dilute solutions the electrostatic capacity of the containing cell is a source of disturbance, which may, however, be obliterated by introducing a small condenser of adjustable capacity.—The temperature coefficient of the dielectric constant of pure water, by F. Heerwagen. This was investigated with a kind of differential electrometer, in which two needles were suspended by one wire in two electrometers arranged vertically one above the other. The needles, the vessel, and one pair each of the quadrants were joined to one point in a constant voltaic circuit, and the other pairs to two other points. The lower electrometer was alternately empty and filled with pure water. Under these circumstances the ratio of the sensibilities was inversely as the ratio of the squares of the differences of potential. The value obtained for K was $80{\cdot}878 - 0{\cdot}362\,(t - 17)$, where t is the temperature of the water in degrees centigrade.—Polarising effects of the refraction of light, by K. Exner. Glass gratings, necessary in order to obtain a sufficiently large angle of diffraction, have the disadvantage of producing polarisation effects due to change of medium in addition to those due to diffraction. This difficulty was overcome by attaching the cut surface to a semi-cylindrical lens by a drop of oil of the same refractive index. The polarisation effects show a fair agreement with Stokes's cosine law.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 8.—"The Process of Secretion in the Skin of the Common Eel," by E. Waymouth Reid, Professor of Physiology in University College, Dundee.

By special attention to the condition of the fish at the time of fixation of their skins for histological investigation, the author has succeeded in obtaining pictures of the various phases of secretory action. The *lowest* phase of activity was obtained by rendering hybernating fish suddenly motionless by a successful transfixion of the medulla, and then removing skin before recovery from "shock" admitted of reflex secretion. The *highest* phase of secretory action was produced by artificial stimulation of the intact animal by the vapour of chloroform, by faradisation, or by simply allowing a pithed summer eel to "slime" after recovery from the primary "shock." The following are the main conclusions:—

(1) The secreting elements of the epidermis of the common eel consist of goblet cells and club cells, both direct descendants of the cells of the palisade layer. The former supply a mucin, the latter threads and a material appearing as fine granules in the slime.

(2) The goblet cells contain mucin granules, and, after reaching the surface and discharging their load, are capable of undergoing regeneration by growth of the protoplasmic foot and re-formation of mucin.

(3) The threads of the slime resemble those of *Myxine glutinosa*, but are usually of finer texture. As in *Myxine*, they are developed from the club cells, but there are no special glandular involutions of the epidermis. The club cells of *Petromyzon fluviatilis* also supply slime threads.

(4) The granular material of the slime is the contents of vesicular spaces developed in the club cells in the immediate neighbourhood of their nuclei, and is set free enclosed in a lattice work developed by vacuolation of the surrounding material, and finally extruded, carrying with it the original nucleus of the club cell.

(5) The remainder of the club cell, after extrusion of its vesicle and nucleus, becomes a spirally coiled fibre, which finally breaks up into the fine fibrils of the slime.

(6) Severe stimulation, especially by the vapour of chloroform applied to the intact animal, causes so sudden a development of the coiled fibres from the club cells that the surface of the epidermis is thrown off and the secretory products set free *en masse*. This process is of reflex nature, for similar excitation applied to excised skin is without effect.

(7) A system of connective tissue cells, distinct from chromatophores, exists in the epidermis developed from cells which are direct descendants of leucocytes, and which can be traced from the blood vessels of the corium through the basement membrane into the epidermis. The number of these wandering cells in the epidermis is greatly increased by stimulation, probably with a view to providing subsequent support to the secretory elements during regeneration.

The paper was illustrated by photo-micrographic lantern slides.

June 15.—"On the Ratio of the Specific Heats of the Paraffins and their Monohalogen Derivatives." By J. W. Capstick, D.Sc. (Vict.), B.A. (Camb.), Scholar and Coutts-Trotter Student of Trinity College, Cambridge. Communicated by Prof. J. J. Thomson, F.R.S.

The object of the experiments was to throw light on an obscure point in the kinetic theory of gases, viz. the distribution of energy in the molecule.

From the ratio of the specific heats we can calculate the relative rates of increase of the internal energy and the energy of translation of the molecules per degree rise of temperature, by the well-known formula, $\beta + 1 = \dfrac{2}{3(\gamma - 1)}$, where γ is the ratio of the specific heats and β the ratio of the rate of increase of the internal to that of the translational energy.

In order to make the results comparable it was decided to keep the translational energy constant by working at a constant temperature—the temperature of the room.

The ratio of the specific heats was calculated from the velocity of sound in the gases. This was determined by Kundt's method, a double-ended form of apparatus similar to that described in *Pogg. Ann.* vol. cxxxv. being used.

The calculation requires the density of the gas to be known, a circumstance which makes the method very sensitive to small amounts of impurity. Regnault's value of the density was used for methane and the theoretical value for ethane, an analysis of the gas being made after each experiment to determine the correction for the air that was unavoidably present. All the other gases were freed from air by liquefaction immediately before being admitted into the apparatus, and the vapour density of the material in the state in which it was used was determined by a modified form of Hofmann's apparatus, which gave results concordant to one part in a thousand.

The formula used in calculating the ratio of the specific heats was

$$\gamma = 1{\cdot}408 \times \rho \times \left(\frac{l}{l'}\right)^2 \left(1 + \frac{1}{p}\frac{d}{dv}(pv)\right),$$

the last factor being added to the ordinary formula to correct for the divergence of the gas from Boyle's Law.

The correction is obtained at once by putting in the equation

$$u^2 = -\gamma v^2 \left(\frac{dp}{dv}\right)_t \text{ the value of } \left(\frac{dp}{dv}\right)_t \text{ given by the equation}$$

$$\left(\frac{dpv}{dv}\right)_t = p + v\left(\frac{dp}{dv}\right)_t.$$

From the vapour density determinations a curve is constructed giving pv in terms of v, and the slope of this curve at any point gives the value of $\frac{d}{dv}(pv)$ in arbitrary units. Dividing by the corresponding value of p in the same units, we obtain the amount of the correction.

The correction increases the ratio of the specific heats by from 1 to 2 per cent. in most cases.

Observations varying in number from three to nine were made on each gas, the extreme range of the values being 2 per cent. for marsh gas, 1½ per cent. for methyl iodide, and 1 per cent., or less, for the rest.

The mean values of the ratio of the specific heats are shown in the following table:—

Methane	CH_4	1·313
Methyl chloride	CH_3Cl	1·279
Methyl bromide	CH_3Br	1·274
Methyl iodide	CH_3I	1·286
Ethane	C_2H_6	1·182
Ethyl chloride	C_2H_5Cl	1·187
Ethyl bromide	C_2H_5Br	1·188
Propane	C_3H_8	1·130
Normal propyl chloride	nC_3H_7Cl	1·126
Isopropyl chloride	iC_3H_7Cl	1·127
Isopropyl bromide	iC_3H_7Br	1·131

From this table we have the result that the gases fall into four groups, the members of any one group having within the limits of experimental error the same ratio of the specific heats.

These groups are—

I. Methane.
II. The three methyl compounds.
III. Ethane and its derivatives.
IV. Propane and its derivatives.

If the members of a group have the same ratio of the specific heats, we know that the ratio of the internal energy absorbed by the molecule to the total energy absorbed, per degree rise of temperature, is the same for all. Hence we have the result that, with the single exception of marsh gas, the compounds with similar formulæ have the same energy-absorbing power, a result which supplies a link of a kind much needed to connect the graphic formula of a gas with the dynamical properties of its molecules.

From the conclusion we have reached, it follows with a high degree of probability that the atoms which can be interchanged without effect on the ratio of the specific heats have themselves the same energy-absorbing power, their mass and other special peculiarities being of no consequence. Further, the anomalous behaviour of methane confirms what was clear from previous determinations, namely, that the number of atoms in the molecule is not in itself sufficient to fix the distribution of energy, and suggests that perhaps the configuration is the sole determining cause.

If this is so, it follows that ethane and propane have the same configuration as their monohalogen derivatives, but that methane differs from the methyl compounds, a conclusion that in no way conflicts with the symmetry of the graphic formulæ of methane and its derivatives, for this is a symmetry of reactions, not of form.

"On Interference Phenomena in Electric Waves passing through different Thicknesses of Electrolyte." By G. Udny Yule. Communicated by Prof. G. Carey Foster, F.R.S.

In the spring of 1889 Prof. J. J. Thomson published [1] a description of some experiments made by him for comparing the resistances of electrolytes to the passage of very rapidly alternating currents, the method consisting in comparing the thicknesses of layers of different electrolytes which were equally opaque to Hertzian radiation. During last winter I made trial of an arrangement identical in principle but more completely analogous to Hughes' induction balance. The method seemed, however, to offer several difficulties and disadvantages, and finally I adopted another, also, one may say, analogous to Prof. Thomson's, inasmuch as it measures transparencies, but in outward appearance completely different from his.

The wires B, F, D, about 1 mm. diameter, were spanned 6 cm. apart. If these wires be made too short, a wave-train emitted from B, B′ may reach the electrolyte x_1, or the bridge D, be reflected, and return to B before the primary has practically done oscillating. If this occur, the state of the secondary may affect the primary as in an alternate current transformer. If, however, Bx_1 be made longer than half the effective length of the wave-train, the reflected waves will not reach B until the primary oscillations have practically come to rest, and under these circumstances the latter will know nothing about any alternations in the secondary at or beyond x_1. This reaction of the secondary on the primary had been first noticed, and to a serious extent, by Herr J. Ritter von Geitler [1] with an exciter of the type used by Blondlot.[2]

In the actual apparatus the wires were at F_1 run out through a window in a loop of about 50 m. circumference round the laboratory garden. They re-entered the room at F_2 and were then run vertically through the vessel for containing the electrolyte. The circuit was completed by another loop, F_3F_4, 50 m. long, round the garden, re-entering the room at F_4, connecting to the electrometer at E, and bridged at D, 2·25 m. = $\frac{1}{4}\lambda$ from the electrometer. According to the researches of Bjerknes (*loc. cit.*) these dimensions should be sufficient, with the present apparatus, to prevent any sensible reaction.

The electrometer was the same one as that used by Bjerknes in his researches in the same laboratory. It is a simple quadrant electrometer with only one pair of quadrants and an uncharged aluminium needle of the usual shape suspended by a quartz fibre. One quadrant is connected to each wire. The needle taking no account of sign, elongations are simply proportional to the time integral of the energy: first throws, not steady deflections, are read.

Various glass jars were used for holding the electrolyte. The wires were run vertically through holes drilled in the bottom of the jar, into which they were cemented.

Several trials were made of this apparatus with dilute solutions of copper sulphate. Readings were taken in pairs alternately, with no solution in the jar and with some given thickness; usually about ten readings at each point. The ratio of the transmitted intensities so obtained was determined for several points and plotted as a curve. Some 5 or 6 cm. of electrolyte was the maximum thickness that could be used in these first experiments. The curves so obtained for these badly-conducting solutions always differed sensibly from the log-arithmic, and the more so the more the solution was diluted. If the mean log. dec. over the whole thickness was taken, the corresponding value of the specific conductivity appeared extremely high.

It appeared likely that these irregularities might be due to interference effects analogous to Newton's rings (by transmission), or the phenomena of "thin plates," particularly in view of the

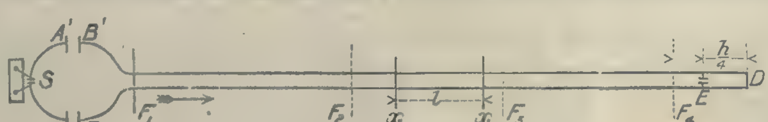


FIG. 1.

Let ASA′ be a Hertz exciter, and B, B′ secondary conductors similar to the primary from which a pair of long wires, stretched parallel to each other, are led off to a considerable distance. One may regard the wires simply as guides for the radiation, which then travels straight up the space between them. If we run these wires for a certain length, l, through an electrolyte, the radiation will have to traverse this and will be partly absorbed. If an electrometer be connected at E, a quarter wave-length from the bridge at the end of the wires, readings taken with various thicknesses of electrolyte should, according to my expectations, give a logarithmic curve, from which the specific resistance would be at once calculable.

The actual dimensions of the exciter, &c., erected were the same as those use by Bjerknes.[2]

A, A′, B, B′ circular zinc plates, diameter	40 cm.
Distance from A to B	30 „
Length of wire ASA (2 mm. diameter)	200 „
Wave length, λ	900 „

[1] "Roy. Soc. Proc.," vol. xlv. p. 269, 1889.
[2] *Wiedemann's Annalen*, vol. xliv. p. 513, 1891.

results obtained just previously by Mr. E. H. Barton in the same laboratory. I consequently desired to investigate for such interference phenomena over as great a thickness of electrolyte as the absorption would permit of using. Distilled water offered itself naturally as the best electrolyte for this purpose.

For the containing vessel a glass cylinder 114 cm. high was used; the internal diameter varied somewhat, but was about 12 cm. at the narrowest.

With this apparatus a series of observations were made for various thicknesses of distilled water. To cover, as far as possible, irregularities in sparking, readings were now taken in pairs alternately at the point to be determined and some other point taken for the time as the standard; it would have caused too great delay, and consequent irregularity in the effectiveness of the sparks, were all the water to be siphoned out between each pair of readings. As before, ten or twelve readings were usually taken at each point. The throw obtained with no liquid was also always taken as unity.

As a specimen of the usual spark variations, the following

[1] Doctor-Dissertation, Bonn, Jan. 1893, p. 22.
[2] *Compt. Rend.*, vol. cxiv., p. 283, Feb. 1892.

series of readings for the determination of the throw with 55 cm. water with reference to 40 cm. will serve. The series is taken quite at random from the others.

40 cm.	55 cm.
4·6	11·4
4·9	11 4
5·0	11·0
4·2	11·9
4·3	11·5
3 9	11·2
4·0	11·6
4·3	11·4
4 6	10·4
4·4	11·2
4·5	10·4
4·6	10·0

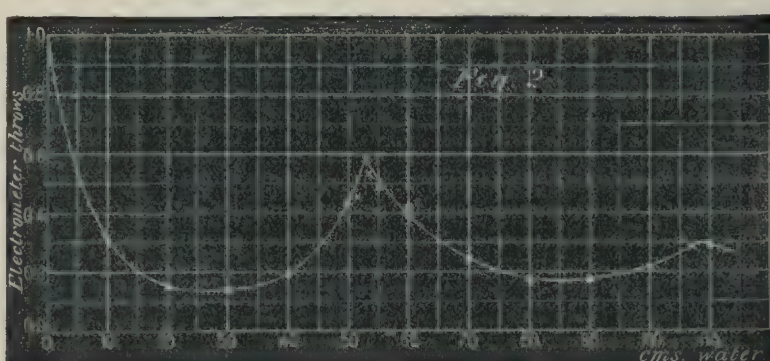
The readings are grouped separately, but it will be understood that they were taken in pairs alternately.

The complete results are given in the curve (Fig. 2). It is seen that for such a poor conductor as distilled water the interference completely masks the absorption effects. The intensity of the transmitted ray does *not* steadliy decrease; on the contrary, far more may be transmitted through a thick than through a thin layer of the absorbent medium. The transmission follows the same general law as for light with a thin plate; we are, in fact, dealing with a "thin" plate—a plate whose thickness is comparable with the wave-length. The intensity of the transmitted ray is a minimum for a plate $\frac{1}{4}\lambda$ thick, a maximum for $\frac{1}{2}\lambda$ thick, a minimum again for $\frac{3}{4}\lambda$, and so on.

The points on the curve round the maximum at $\frac{1}{2}\lambda$ are somewhat irregular, and the two maxima do not absolutely agree. Excluding the Russian physicist as a negligible majority, it will be seen that my value of κ is somewhat low. The cause may lie in the fact that not the whole of the field surrounding the wires lies in the water.

The uncertainty due to this stray field might be easily avoided in one way, namely, by making one wire into a tube surrounding the other, and using this tube also as the jar for the electrolyte. This was, in fact, the arrangement originally intended to be adopted. Several disadvantages attended it, however, and led to its final rejection in favour of the simple wires and glass jar. First, such a condenser reflects under all circumstances a considerable portion of the incident energy.[1] Secondly, the variation of the position of the top surface of the electrolyte relatively to the top of the jar would introduce fresh interference phenomena. This appeared directly from the work of Mr. Barton to which I have already had occasion to refer. Lastly, the large surface of metal in contact with the liquid would render distilled water rapidly impure.

This investigation was carried out in the Physical Institute of the University of Bonn. I desire particularly to express my thanks to Prof. Hertz for his most useful advice and suggestions.



Taking the mean, we may say the wave-lengths in air and water are respectively:—

$$\lambda_a = 900. \qquad \lambda_w = 108 \text{ cm.}$$

This gives us for the coefficient of refraction and the dielectric constant—

$$n = 8{\cdot}33. \qquad \kappa = 69{\cdot}5.$$

The following are the values of K found by previous investigators, all that are known to me:—

1 J. Ritter von Geitler, Doctor-Dissertation, Bonn, Jan., 1893.

Chemical Society, June 1.—Dr. Armstrong, President, in the chair. The following papers were read:—On azo-compounds of the ortho-series, by R. Meldola, E. M. Hawkins, and F. B. Burls. The constitution of the orthazo-compounds is still unsolved owing to the contradictory results obtained by different investigators using different methods. The azo-β-naphthols have been represented by the formulæ X . NH . N : $C_{10}H_6$: O and X . N_2 . $C_{10}H_6$. OH. The principal evidence in favour of the former hydrazone formula was furnished by Goldschmidt and Brubacher; it is, however, rendered invalid by the authors' experiments. On reducing an acetyl derivative of the form X . N_2 . $C_{10}H_6$. OC_2H_3O or X . $N(C_2H_3O)$. N : $C_{10}H_6$: O with zinc dust and acetic acid, four products result, viz.:—X . NH . C_2H_3O, $C_{10}H_6(NH . C_2H_3O)$. OHβ, X . NH_2 and $C_{10}H_6$. NH_2 . OHβ.—The production of a fluorescein from camphoric anhydride, by J. N. Collie. On heating camphoric anhydride with resorcinol and a small quantity of zinc chloride at 180°, a fluorescein is obtained having the composition $C_{22}H_{22}O_5$; it is a reddish powder with a greenish lustre and shows a beautiful green fluorescence in dilute aqueous solutions.—Researches on the terpenes, III. The action of phosphorous pentachloride on camphene, by J. E. Marsh and J. A. Gardner. Camphene and phosphorus pentachloride interact at ordinary temperatures, yielding a compound of the composition $C_{10}H_{15}PCl_4$; on treatment with water a product is obtained from which two crystalline isomeric camphenephosphonic acids, $C_{10}H_{15}PO_3H_2$, have been isolated. On heating camphene with phosphorus pentachloride, a crystalline substance, $C_{10}H_{14}PCl_3$ is obtained; on treating this with sodium carbonate, a salt of the composition $C_{10}H_{14}ClPO_2NaH$ results, whilst on oxidation it yields chlorocamphenephosphonic acid, $C_{10}H_{14}ClPO_3H_2$.—The composition of a specimen of jute fibre produced in England, by A. Pears, junr.—Note on the combination of dry gases, by W. Ramsay. In connection with the results recently obtained by Baker, the author states that in 1886 he recorded the fact that dry hydrogen chloride does not combine with dry ammonia, even in presence of solid ammonium chloride.—Ortho-, para-, and peri-disulphonic derivatives of naphthalene, by H. E. Armstrong and W. P. Wynne. By displacing the amido-group in a naphthylamine derivative by SH and oxidising the resulting thioderivative, a sulphonic group enters the position previously occupied by the amidogen. By means of this reaction the authors have prepared and characterised the 1 : 1′, 1 : 2 and 1 : 4 naphthalenedisulphonic acids; nine out of the theoretically possible ten of these isomerides are hence now known. The 2 : 2′ : 3′ naphthalenetrisulphonic acid has been prepared by a similar method. The corresponding sulphonic chlorides and other derivatives of the above acids are also described.—Supplementary notes on madder colouring matters, by E. Schunck and L. Marchlewski. In 1853 Schunck obtained from madder a yellow colouring matter which he termed rubiadin; it is now shown that madder contains a glucoside of rubiadin, having the composition $C_{21}H_{20}O_9$. It yields a pentacetyl derivative, and on hydrolysis, is converted into rubiadin and dextrose. $C_{21}H_{20}O_9 + H_2O = C_{15}H_{10}O_4 + C_6H_{12}O_6$.—The constitution of rubiadin glucoside and of rubiadin, by L. Marchlewski. The author proposes a formula for rubiadin glucoside, and notes that on heating a mixture of symmetrical metadihydroxybenzoic acid, paramethylbenzoic acid, and sulphuric acid, he has obtained a substance isomeric with and closely resembling rubiadin, but melting at a lower temperature.

Physical Society, June 23.—Prof. A. W. Rücker, F.R.S., President, in the chair.—Mr. F. H. Nalder exhibited a bridge and commutator for comparing resistances by Prof. Carey Foster's method, the chief features of which are simplicity, compactness, long range, and great accuracy. The commutation of the coils to be compared is effected by mercury cups, the eight holes necessary for this purpose being arranged in a circle. An ebonite disc carrying the four connectors is mounted on a spindle in the middle of the circle, and the positions of the coils are interchanged by rotating the disc through 180°. A large range is secured by providing a number of interchangeable bridge wires, and a fine adjustment for the galvanometer key enables great accuracy to be attained.—Mr. W. R. Pidgeon and Mr. J. Wimshurst each read a paper on an influence machine, and exhibited their machines in action. In designing his machine, Mr. Pidgeon has endeavoured—first, to make the capacity of each sector large when being charged, and small when being discharged; second, to prevent leakage from sector to sector as they enter or leave the different fields of induction; and third, to increase the capacity of the machine by making the sectors large and numerous. The first object is attained by arranging fixed inductors of opposite sign to the sectors near the charging points, and of the same sign near the places of discharge. Objects 2 and 3 are secured by embedding the sectors in wax, run in channels in the ebonite discs which form the plates of the machine, and carrying wires from each sector through the ebonite, each wire terminating in a knob. In this way the sectors can be placed much nearer together than otherwise without sparking back. By setting the sectors skew with the radius they are caused to enter the electric fields more gradually, consequently the potential difference between adjacent sectors is kept comparatively small. Experiment showed that the use of the stationary inductors at the charging points increased the output threefold, and as compared with an ordinary Wimshurst, the output for a given area of plate passing the conductors was as 5·6 : 1. The recovery of the machine after a spark had occurred was particularly rapid. Mr. Wimshurst's new machine consists of two glass discs 3 feet 5 inches diameter, mounted about ⅝″ apart on the same spindle. Both plates turn in the same direction. Between the discs are fixed four vertical glass slips over 4 feet long, two on each side, and each covering about ⅛th of a disc. Each slip carries a tinfoil inductor, which has a brush touching lightly on the inside of the adjacent disc on its leading edge. Collecting and neutralising brushes touch the outsides of the discs, and the few metallic sectors attached thereto. An account of some experiments made to determine the efficiency of the machine was given. The author also showed that when all the circuits of the machine were broken, it still continued to excite itself freely, and sparked from the discs to the hands when brought near. In a written communication, Prof. O. Lodge said his assistant, Mr. E. E. Robinson, constructed a machine on lines similar to Mr. Pidgeon's a few months ago, and had now a large one nearly completed. Mr. Robinson's fixed inductors are carried on a third plate fixed between the two movable ones. The sectors are quite small, and neither they nor the inductors are embedded. On close circuit the machine gives a large current ($\frac{1}{10000}$ ampère), and on open circuit exceedingly high potentials. In Dr. Lodge's opinion, Mr. Pidgeon attaches too much importance to his sectors and their shape. Mr. J. Gray wrote to say that stationary inductors enclosed in insulating material would probably give trouble at high voltages, because of the surface of the insulator becoming charged with electricity of opposite sign to that on the inductor. He suggested that this might explain why Mr. Pidgeon could not obtain very long sparks. Prof. C. V. Boys inquired as to how far the wax made insulating union with the ebonite, for if good, glass might possibly be used instead of ebonite. He greatly appreciated the design of Mr. Pidgeon's machine. After some remarks by the president on the great advances which had been made, Mr. Pidgeon replied, and Mr. Wimshurst tried some further experiments with a small experimental machine.—A paper on a new volumemometer, by Mr. J. E. Myers, describing the developed form of Prof. Stroud's instrument, was, in the absence of the author, taken as read.—Mr. R. W. Paul exhibited a compact form of sulphuric acid voltameter of small resistance. The voltameter is a modification of a pattern designed at the Central Institution, in which the rate of decomposition is determined from the time required to fill a bulb made in the stem of a thistle funnel. He also showed a handy form of Daniell cell devised by Prof. Barrett. When not in use, the porous pot containing the zinc is removed from the copper sulphate solution and placed in a vessel containing zinc sulphate or sulphuric acid. A paper on long-distance telephony, by Prof. J. Perry, F.R.S., assisted by H. A. Beeston, was read by Prof. Perry. The case of a line of infinite length, having resistance capacity, self-induction, and leakage, is taken up, and the state of a signal as it gets further and further away from the origin is considered. Taking the shrillest and gravest notes of the human voice to have frequencies of about 950 and 95 respectively, the distance from the origin at which the ratio of the amplitudes of these high and low frequency currents is lessened by $1/m$th of itself, has been determined when $m = 4$ for different values of leakage and self-induction; and under similar conditions the distances at which the relative phase of the two currents become altered by $1/n$th of the periodic time of the most rapid one, have been worked out for $n = 6$. The results are given in the form of tables, from which it appears that if there was no self-induction, increasing the leakage increases the distance to which we can telephone, whilst if there was no leakage increasing the self-induction increases the distance. When self-induction and leakage are not too great, increasing either increases the distance, and for particular values the distances become very large. At the end of the paper tables of general application are given, from which the limiting distances for any line can be readily found by multiplying the numbers by simple functions of the constants of the line. Mr. Blakesley said that some ten years ago he discussed the subject, when capacity and resistance were alone considered, and now pointed out that when self-induction and leakage were introduced the equations were still of the same form. He also suggested how terminal conditions on lines of finite length might be easily taken into consideration. Prof. Perry, in reply, said the introduction of self-induction and leakage rendered the calculations very laborious, and that the terminal conditions were much more complicated than Mr. Blakesley supposed.

Zoological Society, June 20.—Sir William H. Flower, K.C.B., F.R.S., President, in the Chair.—The Secretary exhibited and made remarks on two eggs of the Cape Coly (*Colius capensis*) laid in the Society's Gardens.—A head of a rhinoceros from Northern Somali-land was shown by Mr. Walter Rothschild; also a Caspian seal, believed to be the only specimen of this seal in England; and a series of skins of parrots of the genus *Cyanorhamphus* from New Zealand and other islands of the South Pacific. Mr. Rothschild proposed to refer the specimens of this group from the Auckland Islands to a new species to be called *C. forbesi*.—Other objects exhibited and remarked upon were a specimen of the foot of a calf, in which there were three toes springing from a single cannon-bone, by Mr. W. Bateson, some teeth of a ray (*Myliobatis*) from the Lower Tertiaries of Egypt, remarkable for their enormous size, by Mr. A. Smith-Woodward, and a fragmentary skull of a lemuroid mammal from south-east Madagascar with very remarkable characters, by Dr. Forsyth-Major.—A communication was read from Messrs. Hamilton H. Druce and G. T. Bethune-Baker, containing a monograph of the butterflies of the genus *Thysonotis*. This included a revision of the synonymy of the species, descriptions of several new species and varieties, a complete table showing the distribution of the genus, and descriptions of the genitalia.—Among other communications was one from the Rev. H. S. Gorham, containing a list of the Coleoptera of the family *Cleridæ* collected by Mr. Doherty in Burmah and Northern India, with descriptions of new species; and an account of some species of the same family from Borneo, Perak, and other localities, in the collection of Mr. Alexander Fry. Twenty-eight species were described as new.—Prof. G. B. Howes read a paper on the coracoid of the terrestrial vertebrates. Prof. Howes first spoke of the terminology of the bone commonly called "the coracoid," and then proceeded to the discussion of the mammalian coracoid in particular. He came to the conclusion that it would be best to call the whole ventral coracoidal bar the "coracoid," and to distinguish the doubly ossified type as "bicoracoidal" from the singly ossified or "unicoracoidal" type.—Lieut.-Col. H. H. Godwin-Austen, F.R.S., read the descriptions of some new species of land-shells of the genus *Alycæus* from the Khasi and Naga Hill countries, Assam, Munipur, and the Ruby Mine district, Upper Burmah.—This meeting closed the present session. The next session (1893-94) will commence in November.

PARIS.

Academy of Sciences, July 3.—M. Lœwy in the chair.—Tidal and atmospheric waves due to the action of the sun and of the moon, by M. Bouquet de la Grye. The results are given of a series of determinations of the tides, barometric pressures, and winds made by a French commission at Orange Bay, Cape Horn, ranging at half-hourly intervals from November 1, 1882, to August 31, 1883. A first study of these results confirms the facts, announced previously, relating to luni-solar influence upon the atmosphere. This action is very apparent at Cape Horn, since the water and air at lat. 56° south have a uniform temperature at any given date, and the annual range of temperature is very small.—On the successive deformations of the front of an isolated air wave, during the propagation of the wave along an indefinitely long empty water-pipe, by M. J. Boussinesq.—On birational transformations of algebraic curves, by M. H. Poincaré.—On the observation of the total eclipse of the sun of April 16, made at Joal (Senegal), by M. A. de la Baume Pluvinel.—On a self-registering hydrokinemometer, by M. Clerc. This consists of two vertical cylinders communicating with the water at the stem and the stern of the vessel respectively. The difference of level in the two cylinders is proportional to the square of the velocity with which the boat is travelling. The cylinders are provided with floats, each of which takes a share in actuating the recording pencil, with which they are connected by strings passing over pulleys, disposed in such a manner as to let the record be unaffecting by any heeling or plunging of the boat.—Experimental researches on shipbuilding material, by M. F. B. de Mas.—Radiation of different refractory bodies, heated in the electric furnace, by M. J. Violle.—Auto-conduction, or a new method of electrifying living beings; measurement of magnetic fields of high frequency, by M. A. d'Arsonval.—Additional remarks by M. Cornu.—On chromopyrosulphuric acid, by M. A. Recoura. After showing that the molecule of chromic sulphate can be combined with one, two, or three molecules of sulphuric acid, M. Recoura has succeeded in combining the sulphate with a larger quantity of acid, and has obtained new compounds presenting properties completely different from those of the three former acids, and characters not found in any other chromium compounds. One of these, "chromopyrosulphuric acid," contains five molecules of sulphuric acid.—Constitution of the colouring matters of the fuchsine group, by MM. Prud'homme and C. Rabaut.—On cinchonibine, by MM. E. Jungfleisch and E. Léger.—On mercuric salicylates, by MM. H. Layoux and Alexandre Grandval.—On metallic combinations of Gallanilide, by M. P. Cazeneuve.—On topinambour carbohydrates, by M. Ch. Tanret.—On essence of lavender (*Lavandula Spica*), by M. G. Bouchardat.—Heat of combustion of oil-gas and its relation to illuminating power, by M. Aguitton.—On the genus *Homalogyra*, a type of gasteropod prosobranch molluscs, by M. Vayssière.—On certain physiological effects of unipolar faradisation, by M. Ang. Charpentier.—Experiments on the transmission and evolution of certain epithelial tumours in the white mouse, by M. Henry Morau.—Observations on the preceding note, by M. Verneuil.—Laws of evolution of the digestive functions, by M. J. Winter.—On the histological structure of yeasts and their development, by M. P. A. Dangeard.—On a new process of *Champignon de couche* culture, by MM. J. Costantin and L. Matruchot.—On the glaciers of Spitzberg, by M. Charles Rabot.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Royal University of Ireland Calendar for 1893 (Dublin, Thom).—The Law of Cremation: A. Richardson (Reeves and Turner).—Ostwald's Klassiker der Exakten Wissenschaften, Nos. 41 and 42 (Leipzig, Engelmann).—The Points of the Horse: M. H. Hayes (Thacker).—The Life of a Butterfly: S. H. Scudder (New York, Holt).—Brief Guide to the Commoner Butterflies of the Northern United States and Canada: S. H. Scudder (New York, Holt).—Katechismus der Meteorologie: Dr. Bebber (Leipzig, Weber).—Results of Rain, &c., Observations made in New South Wales during 1891: H. C. Russell (Sydney, Potter).—Results of Meteorological Observations made in New South Wales, 1890: H. C. Russell (Sydney, Potter).—Prodromus Faunæ Mediterraneæ, Vol. 2, Pars 3—Vertebrata: J. V. Carus (Stuttgart, Koch).—Manual of Bacteriology: Dr. S. L. Schenck, translated by W. R. Dawson (Longmans).—Researches on the Zodiacal Light, &c.: Prof. Pickering (Cambridge, Wilson)

PAMPHLETS.—Erster Jahres-Bericht des Sonnblick-Vereines für das Jahr 1892 (Wien).—Transactions of the Astronomical and Physical Society of Toronto for the Year 1892 (Toronto).—Studies on the Life-History of some Bombycine Moths, &c.: A. CONTENTS.

THURSDAY, JULY 20, 1893.

VERTEBRATE EMBRYOLOGY.

Vertebrate Embryology. By A. Milnes Marshall. (London: Smith, Elder, 1893.)

THIS is an eminently practical treatise, designed to assist the senior university student in his laboratory work so as to enable him to gain a thorough knowledge of the successive appearances of the embryos of amphioxus, the frog, the chick, the rabbit, and man, during their course of development from the egg to the adult form. The student is supposed to pursue his studies by the aid of the most modern methods, and he has here placed before him by means of clear methodical description and clever original drawings exactly what he ought to see and identify in his series of microscopic sections. The book will be extremely useful, as are the author's other treatises, to all teachers and students of biology. It should be pointed out that very considerable pains has been taken by Prof. Milnes Marshall to give accuracy and reality to his statements. Especial care has been given to the account of the embryology of the frog, which is illustrated by admirable original drawings and may be regarded as a critical revision of the subject based upon original work carried out by the author and his pupils. Most of the novel features in the chapter on the chick are derived from the work of Duval, but in the later stages of the rabbit's development Prof. Marshall again relies on his own observations and drawings. The account of the human embryo is based upon that of Prof. His with some judicious additions.

I have said that the work is eminently practical, and by that I mean not only that the book is one for the laboratory, but that the author whilst giving the greatest care to accuracy of statement and presentation of fact, has dealt very little—I may even say has avoided dealing—with theoretical questions of wide interest. An introductory chapter in some thirty pages gives a brief and general sketch of the structure of the animal egg, its maturation, its fertilisation, the segmentation of the egg and the germ layers, theories of fertilisation and recapitulation and the origin of sex, and then we settle down to our "types."

I do not doubt that the plan of teaching by "types" has its merits, and has served a very useful purpose; also I cannot doubt that the plan of describing all the phases of an animal's growth (except the adult phase) in order, one after another, has advantages, and perhaps such descriptions constitute—if such a study can really be distinguished and recognised—what is known as "embryology." But it becomes daily more obvious that the histology, morphology, and physiology of the organism must also be considered and treated without regard to the arbitrary separation of adult and embryonic conditions, and without that exclusiveness which the selection of "types" involves. Morphology is essentially *comparative;* it involves the consideration alike of embryonic and adult structure, and must avail itself of the facts of structure exhibited in any and all forms, without being restricted to certain types. It is a consequence of the method of treatment adopted by Prof. Marshall that many interesting morphological problems are not discussed by him. It clearly was not his purpose to consider these problems, but rather to furnish the student with a sound basis of observed fact. At the same time it is a little disappointing—on looking up, in the successive chapters on frog, chick, and rabbit, the account of the development of the urinary and genital ducts—to find no discussion or decisive statement on the author's part as to the morphological relation of these structures, or any suggestion as to the explanation of the divergences in the developmental history of the Müllerian and Wolffian ducts in these "types" respectively, and in other vertebrates. In a work on vertebrate embryology one might reasonably expect such a comparative treatment. Similarly, the question of blastophore and primitive streak and "sickle" is but lightly touched, whilst the conflicting and bewildering accounts of the germinal layers of the mammalian blastoderm are left without further remark than that the account adopted from Rauber and Kölliker, as to what takes place in the rabbit, "is difficult to reconcile with the course of development in other mammals; and further investigation is much needed on these points." It could not be expected that Prof. Marshall should settle in the present treatise all the knotty points of vertebrate embryology, but would it not have been well had he pointed out in some detail the difficulties of reconciliation to which he briefly alludes, and given some indications of alternative solutions of the problems involved? These reflections are by no means to be regarded as depreciation; they are rather intended to illustrate the special lines within which the author has confined his treatise. These being given, it is not too much to say that he has produced a most valuable, clear, and masterly exposition of the known facts of the developmental history of leading types of vertebrata.

Before concluding I may venture to point out two matters which might be amended in a new edition of the book, as well as in the same author's "Practical Zoology." The word "stomatodæum" occurs in several places. There is no reason that I know of for altering the more elegant form "stomodæum" in this way: the one is as "correct" as the other. Being the father of the word "stomodæum" and its twin "proctodæum," I should prefer that those who use it would not delude themselves into the notion that I have inadvertently or ignorantly omitted a necessary syllable in its composition. The second matter is as to Prof. Marshall's figures of transverse sections of adult Amphioxus (Figs. 12 and 13). These require (and have for some time required) correction. The clear space below the black undulated line representing the plaited epithelium of the ventral surface of the atrium should be filled in with shading. It is *not* a space, as it was at one time thought to be, but is a solid mass of gelatinous connective tissue. Moreover, the dotted area marked S in both the figures is not, as the explanation of the figure has it, the cardiac aorta. The space so marked is the sub-endostylar cœlomic space, and the cardiac aorta, which is a relatively small vessel lying within it, is not represented in the figures at all.

E. RAY LANKESTER.

RURAL HYGIENE.

Essays on Rural Hygiene. By George Vivian Poore, M.D., F.R.C.P. (London: Longmans, Green, and Co, 1893.)

EIGHT of the chapters of this work have been, in whole or part, previously published; to these the author has added five others, and the result is a welcome volume, which appeals to all those who take an interest in problems of health.

To the lay reader the book will probably carry conviction upon every one of the many sanitary points which are raised and dealt with, for the writer has a style which is at once clear, incisive, and convincing; and he builds up his conclusions upon good, sound, scientific, and logical bases. Many professed sanitarians will, however, cull here and there from among much which they are unhesitatingly prepared to accept, a little which is not in entire accordance with their own tenets and experience, but which is none the less acceptable as affording much food for thought and speculation.

The keynote struck throughout the work has a genuine ring, for the dominant principles of *rus in urbe* and *urbs in rure* resound through every chapter.

The first chapter deals with the concentration of population in cities, and the author very justly finds great fault with the overcrowding on space that now obtains, and he indicates, upon sound sanitary lines, the conditions which should be imposed to obviate this evil. The advice, however, comes too late for many of our large towns, in which, alas, at the present day, hygiene must needs make way for measures of expediency. Later on, in a capital chapter on "Air," the author resumes his diatribe against overcrowding, and even goes to the extent of facing it in our conventional "at homes." He writes: "Perhaps the day will dawn when it will be considered 'bad form' to give your guests far less than one-twentieth of the fresh air which is allowed to criminals." One is not prepared to unreservedly accept the view that water under pressure and the laying down of sewers have been mainly instrumental in causing overcrowding on space. There can be no gainsaying that our towns, long before the era of the introduction of these two systems, were miserably overcrowded; and there is no reason to doubt that, apart from either of these innovations, the towns would have continued to spread with little or no improvement in this respect, and that, despite the absence of water under pressure, the value of land over certain favoured areas would have insured the appearance of the modern high buildings.

The following principles are powerfully advocated throughout the book: The shallow-earth burial of dead bodies; the payment of water by meter on a sliding scale of charges, giving the "water of necessity" at a low rate, and charging more for the "water of luxury"; that each individual should have at least two-thirds of an acre of land, so as to secure an adequate supply of fresh air, and to provide that all refuse of every kind might be returned to this land in order to maintain and increase its fertility.

The two chapters that deal with personal experiences in a country town are extremely interesting and instructive, as giving the author's experience of a small estate of his own, upon which about a hundred people are housed, and in which he endeavoured—with no small measure of success—to realise his Utopia, *i.e.* a place where there are no sewer pipes; where every cottage has around it an allotment sufficient to be fertilised by, and to purify, all the waste products furnished by the inmates; and in which the waste waters should run "clear as crystal in open channels without needing so-called ventilation."

Throughout the book many interesting agricultural points are raised and treated ably by one who is evidently able to bring considerable practical experience in harmony with theory.

To sum up:—The book is eminently interesting; it is instructive and furnishes much food for the reflective mind, and as such its perusal may be confidently recommended to one and all.

OUR BOOK SHELF.

Die Klimate der Geologischen Vergangenheit und ihre Beziehung zur Entwickelungsgeschichte der Sonne. Von Eug. Dubois. (Nijmegen: H. C. A. Thieme. Leipzig: Max Spohrr, 1893.)

THIS pamphlet is a translation, with additions, of a paper originally published in the Journal of the Dutch East India Company. It consists of two portions of somewhat unequal value and interest. In the first section of the book, extending to thirty-six pages, a short but clear summary is given of the evidence bearing on the question of the climate of former geological periods. The references and notes display complete familiarity with the very large literature which is now in existence in connection with this subject. The second and larger half of the pamphlet, extending to nearly fifty pages, is a well-reasoned development of the theme that the variations in the temperature of the earth's surface during successive geological periods were the result of changes in the heat of the sun, and that the sun is in fact a variable star. Anyone wishing to become acquainted with all the recent facts and arguments bearing on the question of the climate of former geological periods, and to find them carefully summarised, with abundant references to original sources of information, will in this little pamphlet recognise a work admirably adapted to his needs.

Polarization Rotatoire, Réflexion et Réfraction vitreuses, Réflexion métallique. Par G Foussereau. (Paris: Georges Carré, 1893.)

THIS volume consists of a series of lessons given at Sorbonne in 1891-92 to *candidats à l'agrégation.*

Under natural rotatory polarisation the author deals with the fundamental phenomena presented by quartz when traversed by polarised light parallel to the optic axes, and discusses the theories of Fresnel and others relative to rotatory polarisation. The relations between activity and crystalline form, the rotatory power of liquids, and the behaviour of quartz when traversed by light in a direction inclined to the optic axis, are also treated in this section.

Magnetic rotatory polarisation in singly- and doubly-refracting media is discussed in the second part. In both of these sections the effects of the various factors upon which the magnitude of the rotatory power depends—wave length of the light employed, temperature, length and chemical nature of the medium, &c.—are briefly stated.

In the last part is found a discussion of the various hypotheses advanced in connection with the phenomena of vitreous reflection and refraction and of reflection at metallic surfaces.

The book contains a clear account of the theoretical aspects of the above questions, the mathematical treatment being as elementary as is consistent with the nature of the subject.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE *No notice is taken of anonymous communications.*]

The Non-Inheritance of Acquired Characters.

I WISH to call the attention and elicit the opinion of naturalists as to the interpretation of certain facts bearing upon this question.

In my article in the *Fortnightly Review* of May last, p. 664, I give what appears to be a new interpretation of facts which have been often quoted, as to the change in the external characters of a Texan species of Saturnia when the larvæ were fed upon *Juglans regia*, its native food-plant being *Juglans nigra*; and the somewhat analogous facts as to *Artemia salina* being changed into *A. Milhausenii* (the former living in brackish, the latter in salt water) when the water became gradually more salt; the change in this case being progressive, year by year, and proportionate to the change in the saltness of the water. The reverse change was also effected by gradually reducing the salinity of the water inhabited by *A. Milhausenii*.

As regards the former case I remarked in my article as follows:—

"Prof. Lloyd Morgan (in his 'Animal Life and Intelligence,' pp. 163–166) clearly sees that this and other cases do not prove more than a modification of the individual; but it seems to me to go further than this. For here we have a species the larvæ of which for thousands, perhaps millions, of generations have fed upon one species of plant, and the perfect insect has a definite set of characters. But when the larvæ are fed on a distinct but allied species of plant, the resulting perfect insect differs both in colouration and form. We may conclude from this fact that some portion of the characters of the species are dependent on the native food-plant, *Juglans nigra*, and that this portion changed under the influence of the new food-plant. Yet the influence of the native food-plant had been acting uninterruptedly for unknown ages. Why then had the resulting characters not become fixed and hereditary? The obvious conclusion is, that being a change produced in the body only by the environment, it is not hereditary, no matter for how many generations the agent continues at work; in Weismann's phraseology it is a somatic variation, not a germ variation."

I then referred to the marked difference between somatic and germ variations in plants, the former disappearing at once, the latter persisting, when cultivated under abnormal conditions; and also to the cases of many closely allied species of animals and of the races of mankind, which preserve their distinctive characteristics when living and breeding under very different conditions.

The above seems to me a perfectly valid and logical argument, and I was interested to see how it would be met by Lamarckians, who have frequently referred to the same facts as being obviously in their favour, though without any attempt to show how and why they are in their favour. I was therefore rather surprised to read, in the July issue of the *Contemporary Review*, a paper by Prof. Marcus Hartog, in which he characterises my argument as a very bad kind of special pleading, and adds that it amounts to this: "Any change in the offspring produced by altered conditions in the parent is limited to characters that are 'not fixed and inherited'; for fixed and inherited characters cannot be altered by changed conditions in the parent; therefore no experimental proof can be given of the transmission of acquired characters."

The above is of course simple reasoning in a circle, and I cannot recognise it as my reasoning. I have made no general proposition that "fixed and inherited characters cannot be altered by changed conditions in the parent," or that "no experimental proof can be given of the transmission of acquired characters." But I argue that when a decided character is immediately changed by changed conditions of the individual, as in Saturnia, it is not "fixed and inherited." The experiment itself shows that it is not a fixed character, and there can be no proof that it is inherited so long as it only appears under the very same changed conditions that produced it in the parent.

As to experimental proof I believe it to be quite possible. There is one case, which I do not remember having seen referred to, in which nature has tried an experiment for us. I was informed by the President of the Deaf-Mute College at Washington that the male and female students frequently marry after leaving the college, and that their children are rarely deaf-mutes. But the point to which I wish to call attention is the admitted fact that there is usually no disease or malformation of the vocal organs in a deaf-mute. Now, before deaf-mutes were taught to talk as they are now, they passed their whole lives without using the complex muscles and motor-nerves by the accurate coordination of which speech is effected. Here is a case of complete disuse, and there must have been some consequent atrophy. Yet it has, I believe, never been alleged that the children of deaf-mutes exhibited any unusual difficulty in learning to speak, as they should do if the effects of disuse of the organs of speech in their parents were inherited. Here is at all events the material of an experiment ready to our hands. An experiment to show whether the effects of use and disuse were inherited might also be tried by bringing up a number of dove-cot pigeons in a large area covered in with wire netting so low as to prevent flight, at the same time encouraging running by placing food always at the two extremities of the enclosure only, or in some other way ensuring the greatest amount of use of the legs. After two or three generations had been brought up in this way, the latest might be turned out among other dove-cot pigeons, at the age when they would normally begin to fly, and it would then be seen if the diminished wing-power and increased leg-power of the parents were inherited.

No doubt many better experiments might be suggested; but these are sufficient to indicate the character of such as do not require that the offspring be submitted to the same conditions as those which produced the change in the parents, and which thus enable us to discriminate between effects due to inheritance and those due to a direct effect of the conditions upon the individual. The cases of the Saturnia and the shrimps are of the latter kind, and in their very nature can afford no proof of heredity.

ALFRED R. WALLACE.

The Conditions Determinative of Chemical Change: Some Comments on Prof. Armstrong's Remarks.

IN a paper (NATURE, vol. xlviii. p. 237, Proc. Chem. Soc. 1893, 145) bearing the above title, Prof. Armstrong discusses the phenomena of contact action, particularly those of the kind described by Mr. H. B. Baker. The whole discussion appears to us to be based on erroneous conceptions and to call for some criticism, first, on the general position assumed by him and, second, of the details which he brings forward to support that position.

Eight years ago Prof. Armstrong defined chemical action as "reversed electrolysis." It is not clear from his remarks whether this is one of the views which recent observations have led him to modify; but, assuming that he still holds that belief, it may be pointed out that it by no means follows that because an electric current can effect a chemical change, every chemical change is due to or accompanied by electric action. It might as well be argued that because a stone let fall on a glass plate can shiver it, a shivered plate glass always implies a falling stone as its cause—it could be broken by irregular rise of temperature, or by loading it with a too heavy weight, phenomena which imply no expenditure of kinetic energy. Yet the statement contains a germ of truth, but only when so qualified as to amount to something very different. Electrical energy may be absorbed in effecting chemical decomposition; when chemical combination occurs *some form of energy* is made manifest. The facts, apart from theory, as we know them, appear to be these. A certain fraction of some definite amount of electrical energy may be absorbed in producing chemical decomposition, and that fraction will be quantitatively converted into chemical energy; the electrical energy disappears as such, and elements may be liberated from a compound, containing, as elements, the equivalent quantity of chemical energy. These elements may part with their chemical energy, which will then cease to exist as such, but will appear in various forms: some of it may be evolved as heat, some as volume energy, some as kinetic energy, and it is even possible by an appropriate contrivance to obtain a large portion of the chemical as electrical energy. But to state that the energy always passes through the electric stage on its way to other forms in which it manifests itself to us is something altogether different.

The question that Prof. Armstrong tries to answer by the supposition that the presence of an electrolyte is required in order to bring about chemical change admits of a very different reply. We conceive it to be this: In most exothermic combinations the heat evolved is sufficient, provided the change were to proceed adiabatically, to resolve the compound into its constituents. Why, then, should they react? To take a concrete instance:—Why should ammonia and hydrochloric acid combine at ordinary temperatures when the heat evolved by their union is sufficient (*provided none escape*) to raise the reacting molecules to the temperature at which they refuse to combine? For convenience sake the question is stated in terms of heat, since that is the usual form in which the loss of chemical energy manifests itself to us; but it is advisable to keep the statement of the question quite general. It appears to us that the answer is:—because the reaction is not adiabatic. Some substances must be present—the walls of the containing vessel, some compound capable of dissociation, some solid body, such as spongy platinum, which will absorb a portion, perhaps an exceedingly small portion, of energy, and so give the bodies present a chance of interacting without liberating so much energy by their interaction as would decompose the prospective compound. These views, it may be contended, are speculative. It is true: but we venture to think that they are legitimate speculations, involving a complete survey of the circumstances, and not one-sided and partial like those of the paper we are criticising.

Assuming the correctness of Prof. Armstrong's main idea, there are still one or two matters of detail where the assumption scarcely seems in harmony with known facts. He assumes that because hydrogen chloride when dissolved in water forms a composite electrolyte, a gaseous mixture of hydrogen chloride and water will also be an electrolyte. This by no means follows, and indeed experiments which have been made in this direction point to the contrary conclusion. The same holds good of his argument as to the combination of nitric oxide and oxygen—water *vapour* is not known to form a composite electrolyte with gaseous nitric acid.

With regard to the regularity displayed by iodine and hydrogen compared with the irregularity of the results obtained by Victor Meyer with chlorine and hydrogen, it is altogether impossible to understand Prof. Armstrong's attitude. In one sentence he assures us that "this is not surprising," and in the next that "there is a significant [of what?] difference in the behaviour of the two mixtures, as hydrogen iodide should behave as hydrogen chloride." He suggests that some special electrolyte may be active in the case of chlorine and hydrogen; but he is inclined to account for the difference observed from the fact that only one of the reactions is reversible under the conditions of experiment. We quite fail to understand the influence which the reversibility of the reaction would exert on its regularity.

In fine, still assuming for the sake of argument the notion of "reversed electrolysis," we would ask:—In a mixture of hydrogen and oxygen, are the ions there, or are they not there? If not there, will the presence of a *vapour* bring them into existence? If there, what is the need of a so-called impurity? Is it supposed that the impurity will discharge them? Why, then, does not the presence of one or of two conducting wires of the same metal in an electrolyte cause combination of the ions?

JAMES WALKER.

The Corona Spectrum.

IN the preliminary account by M. Deslandres of the main results of the eclipse photographs obtained by the French astronomers at Fundium, as reported in this journal on May 25 (vol. xlviii. p. 81), it is stated that many new coronal lines have been photographed, and that a displacement of the lines in the light from opposite points of the corona in the solar equatorial plane proves a rotational movement nearly corresponding with that of the surface of the sun itself.

In the absence of fuller details it is perhaps a little difficult to accept without reserve these interesting statements, particularly when one considers the somewhat unfavourable conditions under which the photographs were obtained. In the first place, one would like to ask by what means have these new bright lines been identified as belonging to the corona, seeing that, owing to the hazy condition of the air at the above station, the brilliant chromospheric radiations were apparently reflected from a considerable area of the sky in the sun's neighbourhood, forming, as it were, a kind of false corona with a bright line spectrum. So obvious, indeed, is this atmospheric spreading of the chromosphere lines in the spectrum photographs obtained by the English astronomers at the same station, that many lines are shown as clearly on the moon's disk as in the coronal regions; the calcium lines "H" and "K," which are very brilliant chromosphere lines, are in these found to extend considerably above the limits of the true corona, as defined by its continuous spectrum, and are also found equally bright across the dark moon.

From the above considerations one is inclined almost to doubt whether, after all, any true corona lines have ever been proved to exist, excepting perhaps the line 1474 (K), which is not ordinarily a brilliant line in the chromosphere, and would therefore not be easily seen by atmospheric reflexion;[1] and it would seem possible, if not probable, that this beautiful solar appendage, with its dark rifts and curving streamers, shines simply by continuous light.

Definite information on this point would, however, be gladly welcomed by those who are endeavouring to photograph the corona without an eclipse. We would, in fact, clutch at any straw, in the shape of a bright line, in the hope of its yielding a true image of the coronal forms, and it was hoped that the recent eclipse would furnish evidence which would settle this question.

With regard to the second point, namely, the displacement of lines in the coronal spectrum. This is said to be equal to a velocity in the line of sight of 5 to 7 kilometres per second (I presume for the total difference of position of the line), say 3 kilometres for the speed of approach or recession at a distance from the solar limb equal to two-thirds of the diameter.

This is certainly a very striking result, and if confirmed by further study would in itself go far to prove the true coronal nature of the line measured. A displacement is conceivable, it is true, under certain conditions, on the assumption that the light is reflected chromospheric light, but this would not exceed a velocity of 1·87 kilometres, whilst the above result comes not far short of an angular rotation equal to that of the disk itself. A point at the distance named would, if rigidly connected with the sun, alternately approach and recede at a speed of about 4·35 kilometres per second.

It would be interesting to know, however, what are the limits of error in these measurements. I gather that a high dispersion was not employed, and it would seem, therefore, that a large uncertainty may be expected; supposing, for instance, that in the original negative the lines H and K are depicted 25 mm. apart, the total displacement corresponding to 7 kilometres per second will only amount to 09 mm.; an error, therefore, of $\frac{1}{30}$ mm., or $\frac{1}{1250}$ of an inch (corresponding to over $1\frac{1}{2}$ kilometres) would materially affect the result; and to come within this limit would require unusually fine definition in the line measured.

In view of the novelty and great importance of the conclusions arrived at by the leader of the French eclipse expedition to Senegal, students of solar physics will await with keen interest, not to say impatience, the publication of a full detailed discussion of the results obtained. J. EVERSHED.

Kenley, Surrey, July 2.

Lord Coleridge and Vivisection.

MY attention has been called to a letter which the Lord Chief Justice has written in support of an endeavour which is being made by a section of the Society for Promoting Christian Knowledge to withdraw from circulation my little work "Our Secret Friends and Foes," recently published in their "Romance of Science Series." Until the Publication Committee of the

[1] It seems pretty certain, however, from the clearly-defined coronal "rings" seen by Prof. Lockyer and others at former eclipses by means of an objective prism, that a more or less uniform gaseous extension must exist far above the chromosphere and prominences; but is this the corona proper?

Society, in which I have every confidence, takes any action in this matter, I have no wish to participate in the controversy, and have but little doubt that the simple publication in your columns of the enclosed correspondence, without any comment from me, will be quite sufficient to enable the readers of NATURE to form a correct opinion as to the manner in which my book has been made to serve the purposes of the Victoria Street Anti-Vivisection Society. PERCY F. FRANKLAND.

University College, Dundee, July 15.

The committee of the Victoria Street Anti-Vivisection Society have issued the following protest to the members of the Society for the Promotion of Christian Knowledge against a work recently published by that Society, and concerning which the Lord Chief Justice has written the letter appended :—

20, *Victoria Street, London, S.W., July* 1893.

Sir (or Madam),—The attention of the Committee of the above society has lately been drawn to a book issued by the Society for Promoting Christian Knowledge entitled "Our Secret Friends and Foes," the author of which, Dr. Percy Faraday Frankland, held a license last year as a practical vivisector.

My committee consider that the following extracts sufficiently show that the book is calculated to encourage the unjustifiable and demoralising practice of experimenting on living animals :—

"Nicolaier was the first to discover that certain bacilli, widely distributed in the superficial layers of soil, were capable when subcutaneously inoculated into mice, guinea-pigs, and rabbits, of setting up symptons typical of tetanus from which they subsequently died." (Page 123.)

"Rabbits and guinea-pigs inoculated with some (spider's) web . . . . died under particularly well-defined symptoms of tetanus." (Page 126).

Again, with regard to the Pasteur methods, which, from their nature, must involve great torture of animals, we read :—

"Numerous investigators have succeeded in calling forth many of the symptoms of a disease by injecting the products of these organisms" (Page 140.)

On page 148 there is the following passage referring to the establishment of Pasteur Institutes :—

"Such institutions have been established in Russia, Hungary, Italy, Sicily, Brazil, Mexico, Turkey, the United States, and Roumania, whilst in Great Britain, to our unutterable disgrace, we are in this respect behind the unspeakable Turk, and the semi-barbarous subjects of the Czar."

That a Pasteur Institute has not yet been established in England, in spite of repeated efforts on the part of the vivisecting school, is greatly to the credit of this country, for such an institution would result in an enormous increase in the number of painful experiments on God's innocent creatures.

My committee are of opinion that the teaching of this book is opposed to the objects of the Society for Promoting Christian Knowledge, and I am directed earnestly to urge you, if you consider the objections to the book are valid, to write the Secretary, Editorial Department, S.P.C.K., Northumberland Avenue, London, W.C., and protest against the continned publication of it.—I am, Sir (or Madam), your obedient servant,

BENJN. BRYAN, Secretary.

The following is the letter from the Lord Chief Justice of England :—

1, *Sussex Square, W., June* 27.

Madam,—I have signed this paper, not exactly with pleasure, for the whole subject is utterly odious to me, but with great willingness. I have never seen any reason to change or qualify the opinions I expressed many years ago in an article on vivisection which your society reprinted. Should the book in question not be withdrawn by the Society for Promoting Christian Knowledge, I shall at once withdraw myself from it, as it will, in my judgement, become a Society for the Promotion of Unchristian Knowledge. Very good men, I am quite aware, take a different view, and will continue to support the society ; but a man, however obscure, must act upon his convictions, especially when they have not been hastily taken up and are not quite ignorantly maintained.—I am, Madam, your obedient servant (Signed) COLERIDGE. Miss Monro.

Oyster-Culture and Temperature.

IT may interest some of your readers to know that there has been an unusually heavy deposit of oyster spat just now on the collectors (tiles) along this west coast of France. Some of the tiles I have seen during the last few days have been very densely crowded over with the little amber-coloured scales. The oyster breeders both at Arcachon and at Point de Chapus, men of long experience, attribute the special abundance of the spat this season to the continuous hot weather.

The calmness of the sea at the time when the embryos were set free may also have had something to do with an unusually large number passing safely through the critical larval stages.

The temperature of the sea on various parts of the oyster "parcs" at Arcachon last Monday was from 80° to 90° F., and out in the open to-day, half-way between the islands of Oleron and Ré, I find it is 72° F. However, it may be hoped that although temperatures like these may be favourable, they are not necessary for successful oyster breeding.

W. A. HERDMAN.

St. Pierre Ile d'Oleron, France, July 7.

The Diffusion Photometer.

IN the discussion before the Physical Society of June 9, a photometer made of paraffin blocks is mentioned as "The Jolly Photometer." I think, however, that this is the photometer described by me in the *Philosophical Magazine* some two or three years ago ; also in the proceedings of the Royal Dublin Society, and exhibited before the British Association on the occasion of their meeting at Bath. I cannot now give exact references, but I must be pardoned for calling attention to the mistake, as it has been made before by a high authority, and seems likely to be perpetuated in England.

It is correctly described in Wiedemann and Ebert's "Physikalisches Praktikum," recently published (p. 217).

Bonn, July 12. J. JOLY.

P.S.—I have no objection to the prefix if written with a small letter.

[We followed the spelling of the word contained in the official report of the Physical Society.—ED.]

ALPHONSE DE CANDOLLE.

THOUGH this notice is somewhat belated, the passing away of a figure so conspicuous as De Candolle in the European world of science cannot be permitted to receive no more sympathetic notice than a bare record of the fact.

Alphonse Louis Pierre Pyramus de Candolle, to give him his full name, died on April 4 at his house in the Cour de St. Pierre at Geneva, in the eighty-seventh year of his age. If his bodily vigour had of late somewhat failed, he preserved his scientific interests and mental activity up to the last. Only the week before his death I received a letter from him, in which there was no indication of failing vitality, and in which he wrote without anxiety of the work that he had in hand.

So many of us have grown up under the shadow of De Candolle, that it seems almost a kind of impiety to sit down and coldly measure his stature. To me it seems that in a manner his death closes an epoch. With him passes away the last great representative of the French School of Botanical Taxonomy—to which, through Bentham, the English was in a great measure affiliated—and which had its root in Lamarck, whom the world in general scarcely realises as a botanist.

Geneva has long been remarkable as the home of a number of families whose members have cultivated science with distinction. These are for the most part descendants of French Protestants who have emigrated from the south of France. Amongst these the De Candolles stand out in pre-eminence ; the third generation still sees them in the front rank of the scientific world.

Alphonse de Candolle's father, Augustin Pyramus, was a man who would have been remarkable in any age. Gifted with astonishing energy and enthusiasm, a singular power of grasping and co-ordinating large masses of detail, and indefatigable industry, his buoyant charm of manner inspired even the citizens of Geneva with interest and conviction in the supreme importance of taxonomic studies.

I know nothing in scientific literature more entertaining and instructive than his *Mémoires* and *Souvenirs*. They supply a striking instance of his irresistible influence. The return of an important collection of original drawings of Mexican plants was demanded by the lender. De Candolle roused the whole of Genevan society to his aid; the city was almost in a ferment till by united co-operation every one of the 1200 drawings had been copied.

The facts to be told of Alphonse de Candolle's life are simple. Born October 27, 1806, at Paris, he took the degree of Bachelor of Science at Geneva in 1825, and of Doctor of Laws with great distinction in 1829. The influence of his legal training probably gave an impress to his work and character all through life. In 1831 he began to assist his father in his duties as Professor of Botany, and he succeeded him in the chair in 1835. He held it till 1850, when he left it, owing to political events. The remainder of his life he passed as a private man of science. But during middle life he fulfilled with dignity, and not without influence, the duties of a citizen which his character and social position in some sort imposed upon him. After serving as a member of the Representative Council of Geneva, he was a member of the Grand Council from 1862 to 1866. He was the first to advocate the "referendum" in political affairs; he exerted himself to effect numerous reforms in economic and sanitary matters; and by obtaining the use of postage-stamps for his Canton he appears to have paved the way for their general introduction into Switzerland.

The earliest and perhaps the best of De Candolle's botanical works is his Monograph of the *Campanulaceæ*, published in 1831. It has stood its ground more solidly than is often the case with the taxonomic work of the time, and its conclusions have been in the main adopted in the later revision of the order by Bentham and Hooker.

In 1841 De Candolle's father died. He had commenced the publication of the *Prodromus* in 1824. The object of this vast undertaking was to give brief diagnostic descriptions of all known plants. Its publication finally settled the question which had long agitated the scientific world as to the supersession of the artificial Linnean system by a natural one. What is called the Candollean sequence is still in general use, though it is confessedly in some respects itself artificial, and only an approximation to a truly natural arrangement. The father had published seven volumes of this classical and indispensable work. The son carried it down to the completion of the Dicotyledons in the seventeenth volume, published in 1873. He saw that no one man could carry out the task single-handed. While formulating a uniform plan and method of procedure, he managed to summon to his aid the systematic botanists of all Europe. In 1847 he was able to claim that he had contributors from England to the Tyrol, and from Montpellier to the Baltic. He took himself no mean share of the work, and if this kind of research affords comparatively little opportunity for the display of genius, Alphonse de Candolle's work is always characterised by qualities of workmanlike accuracy and scholarly finish.

In early life the writings of Humboldt inspired De Candolle, as they have done many young men, with the impulse to travel. Family circumstances, however, forbad it. But the fascination of phyto-geographical problems had taken possession of him, and the vast assemblage of specific forms which continually passed through his hands must have supplied him with inexhaustible food for reflection.

In 1855 appeared his *Géographie botanique raisonnée*, which was the most important work of his life. It would be impossible in a short space to appreciate this justly. It has been complained that it led to no direct conclusion; and it is all but inexplicable that the author missed seeing that the immense mass of facts he had collected really pointed directly to evolution as the key to its explanation. But the character of the man is an element which must not be overlooked. Essentially in method a statistician, he believed these facts, properly marshalled, would evolve their own law. But scientific method, like other calculating machines, will not evolve more than is implicitly put into it. De Candolle, it must be admitted, neither possessed nor had much sympathy with that touch of imagination akin to inspiration, which by some unconscious cerebral integration sees an even wider principle underlying the facts which are contemplated than by any method of manipulation can be educed from them. But it may be doubted whether a study of the Distribution problem would ever have led to evolution directly. The essence of the Darwinian theory was the discovery of a possible, at any rate conceivable, *modus operandi*. This was the result of an attack from the biological side. The phenomena on a large scale which geographical distribution present are too remote from their ultimate cause to immediately suggest it; yet when the principle is grasped they are immediately susceptible of deductive explanation.

Nevertheless, I cannot but regard the *Géographie*, if not as an actual precursor, yet as one of the inevitable foundation-stones of the modern evolution-principle. In the first place, De Candolle dealt more than one heavy blow to Lamarckism. Botanists were impregnated with the idea that plant-distribution was a mere matter of temperature. Adanson had supposed that there was a simple numerical relation between it and growth. Boussingault had gone further and stated that the product of the period of growth multiplied into the mean temperature was a constant. That within limits there is truth in these statements, I myself believe, and for cultural staples the problem is still worth fresh investigation. But the facts will not bear generalisation, and in the field of nature De Candolle saw that they explained little. Other factors, such as light and moisture, must also be taken into account; if he had gone a little further he would have met the "Struggle for Existence."

But De Candolle's most fertile conclusion was the derivative nature of existing floras, and he cites with approval the classical speculations of Edward Forbes on the flora of Western Europe. De Candolle at any rate brought together a mine of accurate information, collected with vast labour without prepossession and marshalled with consummate judgment. He has furnished an armoury from which it will be long before successive students of the subject cease to draw their weapons. Had he taken narrow and pedantic views of specific limitations, he would have left the subject more confused than he found it. But by treating, for example, the aquatic Ranunculi as a group of variable forms of a single species, *Ranunculus aquatilis*, he supplies facts in a shape at once available for the Darwinian student.

De Candolle met Darwin in 1839, and though he maintained a correspondence with him, they did not meet again till 1880, when the former paid a visit to town. Of this he published a touching and in some degree pathetic account in 1882. He makes his submission to the inevitable. I will translate a few words:—

"The existing distribution of species, especially in islands, compelled me to admit, as early as 1855, four years before the appearance of the "Origin of Species," the creation, in certain cases, of new specific forms derived from older ones. I proved to demonstration that the majority of species ascend to periods far more remote than is generally supposed, and that they have passed through both geological and climatic changes. Lyell accustomed geologists to consider small causes, operating through long periods, as competent to produce large effects. The astronomical conception of indefinite time had penetrated natural science. Five or six thousand years counted for little in the history of organised beings. . . . Uncertainty was everywhere. The facts of classification, of palæontology, of geographical distribution, of organogeny ceased to be intelligible. It was necessary to tread through the barrier of a limited time, and of the belief in the permanence of specific forms. *Alors parut Darwin.*"

The influence of Darwin was conspicuously shown in the remarkable book which De Candolle published in 1873, under the title of "Histoire des Savants." He lays botany aside, and going back to the studies of his academic life, starts afresh under the inspiration of the new ideas. But he does this with the same reserve and almost sceptical spirit which characterises all his writings. The facts must evolve their own consequences. He is reported to have said that "he was a botanist by inheritance and a statistician by birth." But he applies to the treatment of his data a statistical method which is positively fascinating in the skill with which it is employed, and the interest of the results to which it leads. I must content myself with a single conclusion, the undoubted validity of which, it seems to me, is often overlooked.

"Heredity neither gives scientific men special nor extraordinary powers; but only that combination of moral and intellectual qualities which may be directed according to circumstances and the choice of the individual to scientific study or to any other serious or definite object." If we slightly enlarge this conclusion by regarding extraordinary aptitude for particular branches of scientific discovery (or any other field of intellectual or artistic activity), as a sort of exceptional sport from an already specialised race, it appears to me that we have the whole root of the matter. A very distinguished man of science has been known to hazard the opinion that if he had turned his attention to law, he would probably have become Lord Chancellor. I think that he only erred on the side of modesty, and that he would equally likely have been Prime Minister.

But I must pass on. In 1880 De Candolle published his *Phytographie.* This is a useful book, indispensable to the taxonomic workshop. It elaborates and enforces the admirable principles of plant descriptive work laid down by Linnæus, which make the study one of no small value as an educational discipline. The book will always have its value as keeping alive an admirable tradition. Would that its example and precepts were more taken to heart by many modern botanists who fail to see that a description is one thing, a luminous and logical diagnosis a totally different one!

Finally, in 1883, De Candolle published his "Origine des Plantes Cultivées." This sprang from his prefatory studies for the *Géographie.* It is an altogether admirable book: not perfect certainly, or complete, and faulty perhaps more especially in the difficult matter of handling the philological evidence. Yet I know of no one who could have put together the material in a more masterly way, or who could have presented the conclusions derivable from it in a form more likely to carry conviction.

Here I must close. As I began by saying, a great figure has passed away. Distinguished in appearance, his manners though reserved, were always exquisitely urbane. If he lacked enthusiasm of a demonstrative sort he made up for it by extreme sobriety of judgment and inexorable persistence. He was singularly kind to all who were disposed to engage in botanical work; and would spare no pains to help and even aid, with his own accumulated materials, those who were willing to undertake a research. He died beloved by his family, revered by his countrymen, and loaded with distinctions. He was a Foreign Member of the Royal Society, a Gold Medallist of the Linnean Society, a D.C.L. of Oxford, and an LL.D. of Cambridge; and the possessor of the order which perhaps confers the greatest distinction on a scientific man, the "pour le mérite" of Prussia. W. T. THISELTON-DYER.

CARL SEMPER.

A GREAT investigator has left us, and one more vacant tablet of the Hall of Fame has received its inscription.

Carl Semper, born July 6, 1832, at Altona, near Hamburg, a son of the celebrated architect, Gottfried Semper, at first destined for the Royal Navy, but afterwards student, graduate, Privat-Docent, and for twenty-five years Professor of the University of Würzburg, has merited eminence as a traveller, a zoologist, a teacher, and an investigator.

The range of his "Thun und Schaffen"—his doing and making—is so wide that but scant justice can be paid to his labours within the short space of this article. As that of a travelled naturalist and the writer of important works of travel his name is honourably known to the geographer, while his investigations in pure zoology are among the most brilliant and weighty of the past thirty years.

Even in this field of science there was a many-sidedness about the observer, impelling him to work for the increase of knowledge in systematic zoology, comparative anatomy, embryology, comparative histology, and physiology.

His travels in the Philippine and Palau or Pelew Islands, for which he expended nearly the half of the large fortune inherited from his father, resulted in many valuable memoirs on various groups of invertebrata, the joint work of himself and others. Semper's "Holothuria," and his special studies of mollusca—a group in which he was a leading authority—may only be mentioned. His book on the "Palau-Inseln im Stillen Ocean" is unfortunately less known—at least, in this country—but in the opinion of good authorities there are few more delightful works of travel, and fewer still in which the observational powers of the naturalist find as full play.

Of Semper's molluscan work only a specialist can speak as it merits. I know not if he completed all that he intended to do, but I have a lively remembrance of the immense stores of material and drawings which he possessed ten years ago.

To experimental physiology he made many contributions in the *Existenz-bedingungen der Tiere* and elsewhere.

But the works of all others which established his reputation as a university professor were undoubtedly those on comparative embryology.

Among these, "Das Uro-genitalsystem der Plagiostomen" is preeminent. In this and other priceless memoirs was laid the solid foundation on which the ten volumes of the *Arbeiten aus dem Zoologisch-zootomischen Institut zu Würzburg* were gradually built up. The intensity and ardour with which he devoted himself to the problems of embryology also laid the beginnings of the long years of ill-health which have just closed with his death.

Though his work cannot be described as having escaped unscathed from the fierce embryological battles of recent years, most of it still stands intact, and is destined to remain, associated with the name of Semper, as part of the classic literature of vertebrate morphology.

With recapitulation embryology he had no sort of sympathy, and his polemics against Haeckel clearly defined his position as an opponent of the so-called "Law of Ontogeny." He was of those whose embryological work is based rather on the idea that organs, not organisms, repeat parts of their ancestral history in their development.

Of the departed master—"Der Chef," as his students affectionately termed him—a pupil cannot write without feeling. Long before his death the great number of his pupils, who had become occupants of University chairs, testified to the success of his training. Profs. Ludwig (Bonn), Braun (Königsberg), Spengel (Giessen), Kennel (Dorpat), Kossmann (Heidelberg), Carrière (Strassburg), and Fraisse (Leipsic), and the Privat-Docenten Ludwig Will, Biehringer, Voigt, Schuberg, and others, still represent the old Würzburg Institute in more than half of the Universities of Germany. Pupils came to him from all parts of the world. Of his contemporaries only two, Albert von Kölliker and Rudolf Leuckart, can claim a longer array of scholars, and none have trained more successful investigators. Among those who pride themselves on their studies in the quaint old rooms overlooking the Neubaustrasse are R. S. Bergh, C. S. Minot, H. Jungersen, Sharp, Strubell, Goronowitch, Grassi, and the cousins Sarasin. From Great Britain came but two, the late Philip Carpenter and the writer.

The peculiarity of Semper's training consisted in this:—The budding zoologist was first thoroughly grounded in comparative anatomy and histology, and then only, after a preliminary trial on some well-worked theme, might he commence independent investigation. The work once begun, the student received abundant criticism but no help, and thus while Semper guided the worker, he never performed the task himself. In this way the memoirs of his pupils came to be not the work of a school in which the master alone was in evidence, but a series of papers dealing with widely divergent questions, and having only this in common that they were built on the same solid basis of elementary knowledge.

Semper was above all the close friend of his pupils, and with them he formed a small "Verein," in which he took considerable pride. The evenings—which usually became early mornings—spent in the little "Alt-deutsche Stube" of the "Zoological Garden" down the Main will not readily fade from recollection. Then it was that the conversation—French, German, and English—more frequently turned to zoological travel, and discussions on current zoology gave place to little lectures on the Philippines and Palau Islands, on Heligoland and the Riviera, on tropical animals and plants. The educational importance of travel to the young zoologist was an ever-recurring topic with Semper. The advice usually had good effect, for most of his pupils have at one time or another made zoological journeys to distant parts of the world—to Ceylon, to Trinidad, to Greenland, the Celebes, and other places.

One of Semper's ideals was a new laboratory with a tropical house for animals. After long treaty with the Government he was happy in obtaining the completion of his wishes—the new Zoological Institute, a building worthy of the architect-zoologist. Three short years ago we who were his old pupils rejoiced with him on the opening of the new abode. Now, as he would bid the fleeting moment stay, he is taken from us. The director's room is vacant, our chief and our "Studentenzeit" are alike memories, on both of which we can only dwell with fondness and affection.

J. BEARD.

NOTES.

WE regret to record that M. Marié Davy died on July 16, at Clamecy, Niévre, at the age of seventy-seven. M. Davy was at one time at the head of the physical-astronomy service of the Paris Observatory, and took a leading part in the protest against Le Verrier's administration in 1870. He published a large number of papers on electrical and astronomical subjects.

PROF. S. P. LANGLEY, Secretary of the Smithsonian Institution, announces that the Institution has secured a table at the Naples Zoological Station for the use of American investigators. The table will be known as the Smithsonian table. Publications resulting from its use will bear the name of the Smithsonian Institution, and such of them as are of sufficient importance will be printed in the "Smithsonian Contributions to Knowledge."

THE munificent gifts of the legatees of Sir Joseph Whitworth to Manchester are to be increased by a sum of £50,000. The amount previously given by them to carry out the scheme of the Whitworth Institute was £105,000. The legatees consider, however, that even their additional donation will need supplementing by the public if the institute is to attain its due importance.

THE International Maritime Congress commenced its second meeting on July 18 at the Institution of Civil Engineers, under the presidency of Lord Brassey. A large number of British and foreign representatives of maritime interests were present, and the outcome of the week's conference will doubtless be of considerable importance. Lord Brassey took for the text of his presidential address the construction and use of breakwaters, and the works that have been undertaken for the improvement of the entrances to ports. Mr. Mundella, M.P., followed with a description of the growth of the mercantile marine service of Great Britain. The Congress then divided into sections for the reading and discussion of papers. Lord Swansea presided over the section dealing with questions relating to the construction of harbours, breakwaters, and general sea-works; and Admiral Colomb is the president of the section devoted to signals, lights, and buoys. The papers read before these two sections were chiefly of a technical character.

AT the recent Congress of Archæological Societies a subject that elicited an interesting discussion was the "Continuation of the Archæological Survey of England." It was announced that the archæological maps of Essex, Lancashire, Cheshire, Surrey, Sussex, and Derbyshire had been considerably advanced since the meeting of last year. Maps are being prepared by societies in Herefordshire, Cumberland, and Westmoreland, on which all interesting antiquities are indicated. A series of symbols has been devised by the Standing Committee for the diagrammatic representation of antique objects and sites, and a resolution was passed expressing a hope that all societies participating in the survey will adopt these symbols and so ensure uniformity. Mr. H. S. Pearson, of the Birmingham and Midland Institute Archæological Society, gave a detailed description of a photographic survey of the county of Warwick. Each photographer who took part in the work was assigned a district of about six square miles, and their pictures were subjected to the criticism of a committee, in order to determine whether they were "worthy of acceptation." Up to now about 1,700 excellent photographs have been taken, and permanent prints of them have been well mounted and presented to the Birmingham Free Library, so that they could be referred to at any time. Mr. Pearson's paper was cordially received, Sir John Evans expressing his warm approval, and bidding all archæological societies throughout the country to "Go and do likewise." The Archæological Institute also held its annual meeting last week. There was a reception at the Guildhall, several excellent luncheons, with pleasurable and doubtless profitable excursions, and a *conversazione* at the Mansion House, so the meeting was a decided success, though no papers were read or discussion raised of scientific moment.

AT the annual meeting of the Wilts Archæological Society, to be held at Warminster on July 25 and two following days, the President, General Pitt-Rivers, F.R.S., will give an account of some excavations he has been recently making in an early camp in Cranborne Chase, near Rushmore, Salisbury, and adjacent to the group of tumuli of the Bronze Age, which were investigated by him in 1880 in conjunction with the late Prof.

Rolleston. The address will be illustrated by plans and sections, and two models will be exhibited showing the entrenchment before and after excavation.

A NUMBER of water-colour drawings, executed by the artists of the Archæological Survey of Egypt, are being exhibited at the residence of the Marquis of Bute, K.T., 83, Eccleston Square, S.W., and will remain on view until Saturday next. The collection of drawings comprise sketches by Mr. Percy Buckman of various sites of historical interest in the provinces of Minich and Assint, a large number of facsimile drawings of wall paintings in tombs of the ancient and middle kingdoms in the same province by Mr. Buckman, Mr. Blackven, and Mr. Howard Carter, as well as many architectural drawings from the tombs by Mr. John Newberry. Cards for admission to the exhibition may be had on application at the offices of the Egypt Exploration Fund, 37, Great Russell Street, W.C.

THE new laboratories at Guy's Hospital were opened on July 17 by Sir John Lubbock, Bart., M.P., F.R.S., a number of men of science being present. In the course of his remarks Sir John Lubbock said that great and brilliant as had been the discoveries in science during the last fifty years, that of the next would be grander still. He based his belief on three grounds. First, because while knowledge was finite science was infinite; secondly, because new processes and inventions were constantly being applied to research; thirdly, the number of investigators was greater and would go on increasing. He hoped that in the laboratories opened that day new steps would be taken in the triumphal progress of science. Sir John Lubbock subsequently presented the scholarships, medals, and prizes, to the successful students, and delivered an interesting address in which he pointed out the necessity of administering kindly advice and sympathy "to a mind diseased" as well as medicine to the body.

MR. R. LYDEKKER is about to visit the museums of Buenos Ayres and La Plata in order to examine the collections of fossil mammals and birds, a grant for that purpose having been made to him by the Royal Society.

THE Japanese section of the Cornwall Counties Fisheries Exhibition, shortly to be held at Truro, is being organised by a committee of the Council of the Japan Society, and promises to be attractive and interesting. Numerous exhibits, illustrating the fisheries of Japan, are now on their way to England, and many collectors of Japanese works of art have promised to lend objects representing fish and fishing.

THE British Consul at Porto Rico has reported to the Foreign Office that it is proposed to hold an exhibition in that city in November next to commemorate the four hundredth anniversary of the discovery of the island of Porto Rico. The exhibits will include agricultural and industrial implements and machinery, and other objects that are or may become articles of commerce. Space will be granted to exhibitors free of charge, and must be applied for by September 1. All exhibits will be admitted free of customs duty.

FROM September 3rd to 6th a meeting will be held at Lausanne in connection with the Société Helvétique des Sciences Naturelles. There will be a general assembly of the Swiss geological, botanical, and entomological societies, and also various geological and zoological excursions. A detailed programme of the excursions can be had on application to one of the Secretaries, Prof. E. Bugnion, or M. A. Nicati, Lausanne.

THE *Société de Topographie de France* intend to erect a statue of Cassini, the author of the first topographical map of France, in the town of Clermont-en-Beauvais (Oise), not far from Thury. It is a remarkable fact that the family of Cassini had, in a century and a half, five representatives as Members of the Academy of Sciences, of which four were directors of Paris Observatory, the third of them—César François Cassini, of Thury (1714–1784),—being the one whose memory will be honoured.

A REUTER'S telegram reports that the steamer *Falcon*, with Lieut. Peary and the members of the American Polar Expedition, sailed on July 15 from St. John's, Newfoundland, for Bowden Bay, the autumn quarters of the expedition.

THE arrangements are now completed for the celebration of the jubilee of the Rothamsted agricultural experiments at the Laboratory, Harpenden-common, on Saturday, the 29th inst., at 3 p.m., under the presidency of Mr. Herbert Gardner, M.P., President of the Board of Agriculture. The proceedings will commence with the dedication by Mr. Gardner of a granite memorial, erected in front of the Rothamsted Laboratory, to commemorate the occasion. Addresses of congratulation will then be presented to Sir John Lawes and Dr. Gilbert on behalf of the subscribers to the Rothamsted Jubilee Fund and various learned societies, including the Royal, Royal Agricultural, Chemical, Linnean, and other leading scientific institutions. Sir John Lawes will also be presented with his portrait, which has been painted by Mr. Hubert Herkomer, R.A., for the subscribers to the Jubilee Fund. Afterwards there will be a reception at Rothamsted by Lady Lawes. The Rothamsted Laboratory, where the ceremony will take place, adjoins Harpenden-common, and is distant about half a mile from the Harpenden station of the Midland Railway Company.

IT is reported that disastrous floods and landslips, caused by heavy rains and cloudbursts, have occurred in Tyrol, the principal scene of destruction being the upper and lower Inn Valleys, the Oetzthal, and the Zillerthal. Many houses have been swept away, together with the inhabitants and their cattle, while others have been buried by landslips.

SOME very heavy falls of rain occurred in the southern part of England on Saturday and Sunday last, owing to the passage of a small and shallow cyclonic disturbance, which travelled quickly to the eastward. The amounts recorded in several localities exceeded an inch within twenty-four hours, while at Eastbourne the fall was from two to three inches, or more than the average amount for the month of July. The accumulation of water at the latter place was due to the intensity of the fall during a short period; the amount recorded during the whole day has frequently been exceeded at other places.

IN a recent number of the new Russian journal (*Archives des Sciences Biologiques publiée par l'Institut Impérial de Médecine Expérimentale à St. Pétersbourg*, vol. i. no. 5) an account is given of the latest endeavours to secure protection against glanders. It would appear from the experiments here recorded that as a means of diagnosing glanders the "malléine" (extracted from cultures of the glanders bacillus) is of great value. On being inoculated into horses suspected of having glanders, and into healthy animals or horses suffering from some other disease respectively, the different effect produced was constant and very clearly defined. In the case of the former, the existence of glanders was indicated by a distinct rise in temperature, from 1°·5 to 3° C., and the formation of a tumour, whilst in the latter the temperature did not rise, or only very slightly, and an insignificant tumour, or none at all, was produced at the place of inoculation. Innumerable experiments on horses by various investigators confirm these results, and as a proof of the importance which is attached to these researches, it may be mentioned that only last September a circular was addressed by the German Government to the commanders of cavalry, ordering the injection of "malléine" into the horses of those regiments where cases of glanders were proved to have occurred.

THE fact that some micro-organisms may stimulate or depress the vitality or virulence of others has been taken advantage of by both Sanarelli and Chantemesse and Widal in their recent researches on immunity and typhoid fever (*Annales de l'Institut Pasteur*, 1892). The typhoid bacillus very rapidly loses its pathogenic properties when cultivated for any length of time outside the living body. Its virulence may, however, be revived by introducing it into an animal along with sterilised cultures of some special organisms. Sanarelli used sterilised cultures of the *B. coli communis*, beginning with 10-12 cc., and gradually diminishing the dose, until the typhoid bacillus, as taken from the last animal, proved virulent without any addition. Sterilised cultures of the *Proteus vulgaris* may, according to Sanarelli, be also used. Chantemesse and Widal obtained the same results by employing sterilised cultures of the *Streptococcus pyogenes*, it having been found by Vincent that in the most serious cases of typhoid fever which he examined the latter was present along with the typhoid bacillus.

THE true origin of contrast colours is still a much-debated question among physicists. The Young-Helmholtz hypothesis of colour sensation assumes that the perception of a contrast colour by which, for instance, a shadow cast by a candle in daylight appears blue, is due to an error of judgment brought about by falsely taking the candle as representing white light and "dividing the difference of tint between the various portions of the surface equally between them." Mr. Alfred M. Mayer, in the *American Journal of Science*, attempts to show by a series of experiments that the perception of contrast-colour is due to purely physiological, and not to psychical causes. Some careful chronograph experiments showed that the perception of a contrast colour did certainly not require more than one-fifteenth of a second. A spark from a Holtz machine, lasting a millionth of a second and 8cm. long, made a grey ring on an emerald green ground appear a bright pink. The spark was also passed between brass knobs placed in front of a piece of silvered mirror half covered with a piece of green glass. The path of the spark presented a remarkable appearance. The portion reflected from the mirror only was white, while the other portion consisted of two images reflected by the green glass and the mirror respectively. The former appeared red by contrast, and the latter was coloured green by transmission through the glass. Thus a white source appeared both white and red at the same instant. The hypothesis of a knowledge of the real whiteness of the surface illuminated partly by a candle and partly by daylight influencing the perception of contrast colours was refuted by arranging such a surface behind a screen and letting two independent observers view it through a tube showing two semi-circles in juxtaposition. They were misled as to what to expect, but they both immediately described the patches as yellow and sky-blue respectively. These experiments tend to confirm Hering's hypothesis, which assumes that when a portion of the retina is stimulated, adjoining portions are affected by a sort of inductive action producing complementary perceptions.

AN interesting note on the variation of the earth's magnetism in the neighbourhood of a hill containing magnetic rocks, by Messrs. Oddone and Franchi, has appeared in the *Annali dell' Ufficio Centrale di Meteorologia e Geodinamica* (vol. xii. part 1). The hill was composed of serpentine, and had, roughly speaking, a lenticular shape, being 1500 m. long and 500 m. broad, with its greatest length north-west and south-east. The declination is the only element up to now observed, and the variation of this element along certain lines has been determined by means of a large compass, to which a telescope, moving in a vertical plane, was attached. The needle, about 16 c.m. long, had a fine pointer attached, and its position was read by means of a scale engraved on looking-glass. A preliminary series of observations, made on ground where there was no disturbance, showed that this instrument could be depended on to within one or two minutes of arc. The method of observing followed was to set up the instrument, and, looking through the telescope, note a series of points, all in a straight line with some distant object, then to clamp the horizontal scale to the telescope support, and read the ends of the needle. The instrument was then transported to the points which had been noted, and the telescope directed to the distant mark. Then the differences in the readings for the needle gave the differences in the declination at the stations along the line. As an example of the magnitude of the deviations obtained we may give the following set of readings (corrected for diurnal variation), along a line running north-east from the hill. At the out-crop of the serpentine the reading for the needle was 11° 20′; about 100 m. away, 10° 35′; about 500 m. away 9° 56′ 30″; while at a distance of 700 m. it was 9° 50′ 30′. In every case they obtained an attraction of the north pointing pole of the needle towards the serpentine, thus indicating that the mass of rock was magnetised with its upper end a south pole.

M. FÉLIX LECONTE has invented a simple form of automatic cut-out, consisting of a cylindrical metal vessel containing mercury and closed at the bottom by a plate of iron held up by springs. A copper rod dips into the mercury and forms one terminal, the current passing through the mercury to the metal cylinder, which forms the other terminal. Beneath the piece of iron an electro-magnet is placed, which is connected with an electric battery, whose circuit is closed at any pre-arranged time by a contact fixed to a clock. When this contact is made, the electro-magnet attracts the iron, allows the mercury to escape, and thus breaks the main current.

A MEMOIR on prehistoric naval architecture of the north of Europe, by Mr. George H. Boehmer, has been issued by the U.S. National Museum. 'Tis "a tale of the times of old," and therefore full of interest to the student of history. Furthermore, it is written with technical knowledge, and bristles with references, and therefore commands the respect of the scientifically-cultured mind. In the memoir the build of thirty ships, discovered in various places, is explained by text and illustration. And the whole discussion indicates that the maritime explorations of the people of the south, the Phœnicians, influenced the character of the naval structures of the ancient inhabitants of Scandinavia. Of all the boats that have been excavated none seem to excel in beauty that found at Gokstad, Norway, in 1880, and now in the Archæological Museum of the Royal Frederichs University at Christiania. In the opinion of experts this boat is a masterpiece of its kind, not to be surpassed by aught which the shipbuilding craft of the present age could produce.

WE have received the first number of *The Physical Review*, a journal of experimental and theoretical physics conducted by Mr. G. L. Nichols and Mr. E. Merritt, and published for Cornell University by Messrs. Macmillan and Co. The new publication is on much the same lines as the *Philosophical Magazine*. It contains five papers on physical subjects, a few notes, and critical articles on several new books. Mr. Nichols writes on the transmission spectra of certain substances in the infra-red, and Mr. B. W. Snow on the infra-red spectra of the alkalies. The relation between the lengths of the yard and the metre form the subject of a paper by Mr. W. A. Rogers. Messrs. S. Sheldon and G. M. Downing write on the critical current density of copper deposition, and the absolute velocity of migration of the copper ions, and Messrs. F. Bedell and A. C. Crehore give a geometrical proof of the three-ammeter method of measuring power. We wish the venture the complete success that its high character merits.

WE have received a copy of "The Brighton Life Table," based upon the mortality of the ten years 1881–90, by Dr. Arthur Newsholme. No previous life-table has been constructed for Brighton, so the vital statistics of 1881-90 could not be compared with those of any preceding decennium. Dr. Newsholme has, however, compared his figures with those for the whole of England and Wales between 1871 and 1880, and also with the 1881–90 life-table of Manchester. The comparison indicates that the probabilities of life among both males and females are at most ages greater in Brighton than elsewhere—a result that might have been expected.

WE learn from the *Victorian Naturalist* that Mr. D. M'Alpine, pathologist to the Victorian Department of Agriculture, is preparing for publication by the Department a *Systematic Census of Australian Fungi*, together with a host-index and list of works on the subject. He is desirous of making the list as complete as possible, and will be pleased to receive from workers any published papers, &c., especially on the microscopic forms. It is proposed to continue the list in annual supplements.

THE 1892 report of the Superintendent of the Royal Botanic Gardens, Trinidad, has been received. The experiments instituted by the Government having shown that tobacco of a suitable character for making good cigars can be grown in Trinidad, enterprising planters are beginning to cultivate a sufficient area to make the crop remunerative. Mr. Hart reports that the quality of the product of the district (always a tobacco producing one) in which the operations were conducted, has much improved. The native cultivators have partially adopted the methods employed by the skilled cultivator, hence it is anticipated that the industry will continue to make progress during future years.

MR. M. DUNN, of Trevagissey, has sent us a paper by him on "The Migrations and Habits of the Pilchard," which appears in the annual report of the Royal Polytechnic Society for 1892.

MESSRS. LONGMAN will shortly publish a work entitled and specially devoted to "The Micro-organisms in Water," by Prof. and Mrs. Percy Frankland. It will deal not only with the presence and significance of bacteria in water, but also with the various means of effecting their removal, and an account will be given of what is known concerning the vitality of pathogenic microbes in various waters. A tabulated description of the micro- and macroscopic characters of all the micro-organisms, both pathogenic and non-pathogenic, hitherto discovered in water will be appended, whilst a special part will be devoted to the methods involved in the bacteriological examination of water. The work is intended to serve as a handbook for all interested in the sanitary aspects of water supply.

A CATALOGUE of books issued by Mr. Charles Lowe, New-street, Birmingham, contains the titles and descriptions of a number of scientific works for sale and wanted.

A CONSIDERABLE number of metallic salts of sulpho-phosphoric acid, H_3PS_4, have been obtained in a pure state by Dr. Glatzel of Breslau, and are described in the current number of the *Zeitschrift für Anorganische Chemie*. They are prepared by heating an anhydrous mixture of the chloride or sulphide of the metal with phosphorus pentasulphide, being produced in accordance with the equations:—

$$3RCl + P_2S_5 = R_3PS_4 + PSCl_3,$$
$$3R_2S + P_2S_5 = 2R_3PS_4.$$

The metallic chloride or sulphide requires to be perfectly dry, if possible being fused previous to the experiment. When cold it is finely powdered, intimately mixed with excess of anhydrous pentasulphide of phosphorus and the mixture heated in a small retort, at first slowly and carefully, finally to low redness. If the chloride of the metal is employed, thiophosphoryl chloride distils over and is condensed in a receiver. The excess of phosphorus pentasulphide sublimes into the neck of the retort, leaving the metallic sulphophosphate behind. The latter is purified from any undecomposed metallic chloride or sulphide by washing first with dilute hydrochloric acid, and afterwards with water, filtering and drying. In this manner the normal sulphophosphates of manganese, zinc, ferrous iron, nickel, cadmium, lead, thallium, tin, copper, silver, mercury, bismuth, antimony and arsenic have been obtained in a pure state. In addition to these, normal potassium sulphophosphate K_3PS_4 has also been obtained, but it was found impossible to separate it entirely from phosphorus pentasulphide; efforts to prepare normal sulphophosphates of sodium, ammonium, barium, strontium and calcium have not yet been successful. The normal sulphophosphates of manganese, zinc, ferrous iron, nickel, cadmium and copper were obtained in the form of crystalline powders, the others as fusible solids, which crystallise upon re-solidification. The zinc and cadmium salts are white, the manganese salt green, the iron, nickel, lead, tin and bismuth salts vary from dark brown or grey to black; the thallium, copper, silver, antimony and arsenic salts are yellow; and mercury sulphophosphate is red and very sensitive to light. The whole of them, with the exception of the potassium salt, are insoluble in water and organic solvents, but are slowly attacked by dilute acids with evolution of sulphuretted hydrogen. The potassium salt is decomposed by water alone with liberation of the same gas. It would appear, indeed, that the more negative metals, such as bismuth, antimony and arsenic form sulphophosphates with the greatest facility. The bismuth salt $BiPS_4$ remains in the retort after distilling a mixture of bismuth chloride and phosphorus pentasulphide as a dark-coloured liquid which solidifies to a grey mass upon cooling, and yields upon pulverisation a powder of the colour of red phosphorus. Antimony and arsenic form similar crystalline sulphophosphates of a yellow colour, which are more volatile, however, and, moreover, may be distilled without decomposition. The arsenic salt solidifies in the receiver in a transparent form resembling amber.

IN attempting to prepare a ferric sulphophosphate by the action of phosphorus pentasulphide upon anhydrous ferric chloride, an unexpected artificial synthesis of iron pyrites, FeS_2, in crystals identical with those found in nature, was effected. The reaction occurs as represented by the equation:—

$$3Fe_2Cl_6 + 2P_2S_5 = 3FeCl_2 + 3FeS_2 + 4PSCl_3.$$

The crystals of iron pyrites were formed as a beautiful glistening sublimate just above the heated portion of the retort. They possessed the usual brass-yellow colour and brilliant lustre, and consisted of pentagonal dodecahedrons and cubes or combinations of these forms, together with faces of the octahedron and of the more complicated forms of the cubic system. Moreover, the same mode of striation was observed as is so characteristic of natural crystals.

NOTES from the Marine Biological Station, Plymouth.—Last week's captures include the Polychæta *Staurocephalus rubrovit-*

tatus and *Sphærodorum peripatus*, the Isopod *Apseudes Latreillii*, the Schizopoda *Mysidopsis gibbosa* and *Hemimysis Lamornæ*, specimens of the Brachyuran *Hyas coarctatus* decked with weeds and compound Ascidians, the Lamellibranch *Arca tetragona*, and the Ascidian *Perophora Listeri*. In the floating fauna little change has been observed, but numbers of the Leptomedusan *Laodice cruciata* have been taken on the beds of Zostera. The following animals are now breeding:—The Hydroid *Coryne vaginata*, the Polychæte *Polycirrus aurantiacus*, the Amphipod *Corophium Bonellii*, the Decapod *Palæmon squilla* and the Lamellibranch *Arca tetragona*.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*, ♀) from India, presented by Capt. R. D. Arnold; a Leopard (*Felis pardus*), a Striped Hyæna (*Hyæna striata*) from India, presented by Capt. Currie; a Malayan Bear (*Ursus malayanus*) from Malacca, presented by Mr. M. O. N. Rees-Webbe; four Prairie Marmots (*Cynomys ludovicianus*) from Texas, four Orbicular Horned Lizards (*Phrynosoma orbiculare*) from California, presented by Mr. G. B. Coleman; a Harnessed Antelope (*Tragelaphus scriptus*, ♂) from West Africa, presented by Mr. A. L. Jones; four Galapagan Doves (*Zenaida galapagensis*) from the Galapagos Islands, an Auriculated Dove (*Zenaida auriculata*) from Chili, presented by Capt. Hedworth Lambton, R.N.; a Guilding's Amazon (*Chrysotis guildingi*) from St. Vincent, W.I., three Boddaert's Snakes (*Coluber boddaerti*), three Carinated Snakes (*Herpetodryas carinatus*) from Grenada, W.I., presented by the Hon. Sir Walter F. Hely-Hutchinson, K.C.M.G.; two Red-tailed Buzzards (*Buteo borealis*) from Jamaica, presented by Mr. Charles B. Taylor; a Crested Porcupine (*Hystrix cristatus*) from Africa, an Australian Cassowary (*Casuarius australis*) from Australia, two Blyth's Tragopans (*Ceriornis blythi*, ♂ ♀) from Upper Assam, deposited; two African Tantalus (*Pseudotantalus ibis*) from West Africa, two Demoiselle Cranes (*Grus virgo*), six Moorish Tortoises (*Testudo mauritanica*) from North Africa, a Secretary Vulture (*Serpentarius reptilivorus*) from South Africa, two Common Rheas (*Rhea americana*, ♂ ♀) from South America, two Cabot's Tragopans (*Ceriornis caboti*, ♂ =) from China, four Crested Pigeons (*Ocyphaps lophotes*) from Australia, purchased; a Mule Deer (*Cariacus macrotis*, ♂), a Martineta Tinamou (*Calodromas elegans*), seven Summer Ducks (*Œx sponsa*), seven Mandarin Ducks (*Œx galericulata*), three Australian Wild Ducks (*Anas superciliosa*), six Magellanic Geese (*Bernicla magellanica*), three Peacock Pheasants (*Polyplectron chinquis*), three Cheer Pheasants (*Phasianus wallichii*), six Gold Pheasants (*Thaumalea picta*) bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

EPHEMERIS OF THE NEW COMET.—Prof. E. Lamp gives the following elements for Quénisset's comet in *Astr. Nach.*, No. 3173:—

$$\tau = 1893 \text{ July } 7{\cdot}3140, \text{ Berlin Mean Time.}$$

$$\left.\begin{aligned} \omega &= 47^\circ\ 6'{\cdot}72 \\ \Omega &= 337\ 20{\cdot}93 \\ i &= 160\ \ 1{\cdot}88 \end{aligned}\right\} 1893{\cdot}0$$

$$\log q = 9{\cdot}82948$$

From these elements the following ephemeris has been computed by Dr. Kreutz:—

1893	R.A. app. h. m. s.	Decl. app. ° ′
July 21	11 27 28	+25 19·1
22	11 32 44	24 1·0
23	11 37 19	22 49·8
27	11 50 50	18 59·8
31	11 59 24	16 12·8
Aug. 4	12 5 18	14 6·2

The comet is decreasing in brightness.

The following communication has been received from South Kensington:—

"The comet was observed by Mr. Shackleton as early as July 11, before any notice of it had been received, but owing to the unfavourable state of the sky he was unable to perfectly satisfy himself that it was a new object. Although the sky was partially clear on July 14, the comet could not be seen from the Observatory as it was unfortunately very low in the north-west, and fell within the glare of the illuminations of the Imperial Institute. On Sunday, July 16, the sky was much clearer, and the comet was easily picked up with a small telescope. Observations with the equatorial, however, were impossible. Its position was roughly estimated as R.A. 10h. 41m., Decl. 33° N., and it was about equal in brightness to a fourth magnitude star. On July 17 the sky was clear, and the comet was observed by Mr. Shackleton with a 6-inch telescope temporarily erected in an elevated position; a faint tail was then observed, extending further on the southern than on the northern side of the axis. Owing to the absence of an equatorial mounting to the telescope employed, spectroscopic observations were very difficult, but three bright bands—probably the well-known bands of carbon which so frequently appear in cometary spectra—were recognised. There was only a very feeble continuous spectrum."

COMET FINLAY (1886 VII.).—The ephemeris of this comet for the ensuing week is as follows:—

12h. *Paris. M.T.*

1893.	R.A. (app.) h. m. s.	Decl. (app.) ° ′ ″
July 20	4 30 54·16	+20 33 51·0
21	35 18·76	20 45 55·3
22	39 41·86	20 57 28·5
23	44 3·43	21 8 31·0
24	48 23·42	21 19 3·0
25	52 41·80	21 29 4·9
26	4 56 58·53	21 38 37·0
27	5 1 13·57	21 47 39·8

OBSERVATIONS OF THE PLANET VICTORIA.—Observations of this planet were specially undertaken in 1889 to determine the mean horizontal parallax of the sun, and afterwards to compare the calculated with the observed places of the planet with the object of proving the existence of a short periodic perturbation, as would occur if, for example, an erroneous value for the lunar equation had been adopted. The observations (*Bulletin Astronomique*, tome x., June 1893) were of three kinds, as Dr. Gill in this note informs us—(1) meridian observations of the planet and comparison stars, made at twenty-one observatories during the opposition in 1889; (2) heliometric triangulation of comparison stars, consisting of measures of the distances of the stars less than 2° apart and measures of the angles of position (these observations were made at the observatories of Yale College, Göttingen, Bamberg, and at the Cape during the year 1890); and (3) heliometric observations of the angular distance of the planet from two comparison stars, one above and the other below the apparent position of the planet in the sky. This work was accomplished by the same observatories with the addition of that at Leipzig.

In this preliminary note, Dr. Gill refers only to the general results of the discussion. The following table shows the values for the mean horizontal parallax of the sun as deduced from the discussion of the observations in groups:—

Group.	Limit of groups.	M.S. parallax.	Rel. weight.	$\Delta\alpha$ C−O.	$\Delta\lambda$ C−O.
		″		″	″
I.	June 10–12	8·723	0·8	—	—
II.	,, 15–19	804	12·3	−0·01	+0·00
III.	,, 19–26	828	15·4	+0·04	+0·02
IV.	,, 26–July 3	872	29·2	−0·02	−0·07

XII.	Aug. 4–10	826	20·0	+0·11	−0·04
XIII.	,, 10–17	816	26·0	−0·05	0·00
XIV.	,, 17–22	819	19·9	+0·04	+0·06
XV.	,, 22–27	8·738	13·3	−0·04	+0·01

The mean of these gives the value

$$\pi = 8''{\cdot}809, \text{ with a probable error of } \pm 0''{\cdot}0066.$$

The observed and calculated positions agree only in the limits of the errors of observations on the assumption "of a periodic term, the period of which is nearly identical with that of the lunar period, and whose maxima and minima occur at epochs when the longitude of the moon differs by 90° from that of the planet. Adopting 6″·40 in place of 6″·50 for the lunar equation, the residuals obtained from the corrected ephemeris and the observations are made very small, as can be seen from the last two columns of the above table.

The correction of −0″·1 in the lunar equation demonstrates, as Dr. Gill says, that the value adopted up to the present for the lunar mass ought to be diminished by one-hundredth.

DIFFERENCE OF LONGITUDE BETWEEN VIENNA AND GREENWICH.—In the fourth volume of the "Publicationem für die Internationale Erdmessung," entitled "Astronomische Arbeiten des k.k. Gradmessungs-Bureau," by Theodor v. Oppolzer, and after his death by Prof. Weiss and Dr. Robert Schram, we are presented with the results of the determination of the difference of longitude between Vienna and Greenwich, and with the Berlin time determinations and the personal equations of the separate observers relating to other longitude determinations, those between Vienna—Berlin—München—Greenwich. We may mention here that, with regard to the first-mentioned determination, another one, between the same places but after a method due to Döllen, by observations in the vertical of Polaris, will appear in a later volume.

The observations for the combined longitude determination between the above-mentioned places were commenced on July 7, 1876, and were completed on September 26 of the same year. Not only was the usual method of procedure adopted, but also that which we owe to Döllen, the instruments used being, for the former method those by Repsold, and for the latter those by Herbst. In the Vienna—Greenwich longitude determination at the beginning and at the end of the observations, time signals, both from Vienna and from Greenwich, were changed with Berlin; in the middle observations Vienna—Greenwich interchanged time signals; and towards the end München was included. In the following table, which gives the results for the single evenings, ΔL represents the longitude between the points of observation and $d\Delta L$ the deviations from the most probable value of the longitude difference:—

Date.	ΔL. h. m. s.	$d\Delta$L. s.
17 July, 1876	1 5 21·037	+0·043
21 ,,	21·028	+0·034
22 ,,	20·995	+0·001
26 ,,	20·955	−0·039
5 Aug.	20·832	−0·162
7 ,,	21·107	+0·113
17 ,,	21·146	+0·152
21 ,,	20·845	−0·149
27 ,,	21·016	+0·022
5 Sept.	21·037	+0·043
11 ,,	21·025	+0·031
21 ,,	1 5 20·902	−0·092

The result obtained, when the points of observations are reduced respectively to the centre of the Greenwich Transit Circle and to the centre of the large dome of the Vienna Observatory is

1h. 5m. 21·421s. ± 0·021s.

PHOTOGRAPHS OF THE MILKY WAY.—Prof. E. E. Barnard, who has recently been on a visit to Europe, has brought with him some wonderful photographs of the Milky Way, which are simply a revelation to many of us. These photographs (*The Observatory*, No. 203) were taken at the Lick Observatory with a lens made by Mr. Willard of New York in 1859, which is one of large aperture (6 inches) and short focus (31 inches). Such a lens tends to compress as well as intensify the characteristic features of these stellar clouds, the large field allowing one to embrace any of these forms as a whole, and not in detail, as is the case when they are viewed with a telescope. The first photographs, showing the cloud forms, were taken in August of 1890, the portion of the sky being that situated in Sagittarius, and the exposure 3h. 15m. A most interesting picture is that of a section of the constellation of Cygnus, near γ Cygni; this photograph shows some of those curious and almost weird dark spots and dark lanes the origins of which are very doubtful. Mr. Ranyard supposes them to be due to an obscuring medium between us and that part of the Milky Way, but Prof. Barnard's opinion is that they are real holes in the cloud structures themselves. Two photographs with different lengths of exposures (2h. 45m. and 4h. 30m.) of the region about M. 11 in the constellation of Sobeski raises an important point as regards the different structure of the Milky Way. The second picture exhibits details which considerably altered the configuration, not at all brought out in the first one. Not only in these photographs, but in several others of the Milky Way, this fact has been noticed, and Prof. Barnard suggests that there may be different orders or kinds of cloud structure implying distance or nearness, or possibly an entirely different order of stars in point of actual size.

THE INSTITUTION OF NAVAL ARCHITECTS.

THE summer meeting of the Institution of Naval Architects was held last week in Cardiff. This is only the fifth provincial meeting held by this Society since its foundation. The first was in Glasgow, the next in Liverpool, and the third in Newcastle. The fourth was held again in Glasgow. All these meetings were eminently successful, and it is somewat strange that the Council should not have made a point of holding a country meeting every year. We believe, however, that it is now the intention to follow that course, and certainly the great success of the meeting held in South Wales last week will support those who advocate two meetings a year.

We propose in our report dealing only with the sittings held for the reading and discussion of papers, but it may be stated that the excursions were very successful. Some of these were of a purely recreative nature, such for instance as that which occupied the whole of the last day, Friday, the 14th inst., when members were taken from Cardiff to Ilfracombe and back by the steamer *Lorna Doone*. The visit to Caerphilly Castle, with the luncheon in the ancient banqueting hall, could not by any means be construed as "business" for naval architects, and the same might be said of the visit to Lord Windsor's grounds at Penarth, illuminated for the occasion.

Mixed with these junkettings, however, there was a good deal of a more serious nature, as the following list of papers read will show:—

(1) "On points of interest in the construction and repair of vessels carrying oil in bulk," by B. Martell, chief-surveyor of Lloyd's Registry of Shipping.

(2) "On fast ocean steamships," by F. Elgar.

(3) Some experiments on the combination of induced draught and hot air, applied to marine boilers fitted with serve tubes and retarders," by J. D. Ellis.

(4) "On wear and tear in ballast tanks," by A. K. Hamilton, of Lloyd's Registry.

(5) "On the transmission of heat through boiler plates," by A. Blechynden, Barrow.

(6) "On water tube boilers," by J. T. Milton, chief-engineer-surveyor to Lloyd's Registry.

(7) "On the theory of thin plating and its applicability to calculations of the strength of bulkhead plating and similar structures," by G. H. Bryan, of Cambridge.

The last paper was not read, but distributed at the meeting, the discussion being deferred until the spring meeting of next year.

On the members assembling at the Town Hall, Cardiff, on the morning of Tuesday, the 11th inst., they were welcomed by the Mayor of Cardiff, and the chair was then taken by Sir Nathaniel Barnaby (late Director of Naval Construction), the President, Lord Brassey, not having arrived. Mr. Martell's paper dealt with various details involved in the construction of oil tank steamers. It would seem at first sight a simple matter to construct a steel vessel capable of carrying oil in bulk; but this is by no means the case, and in trying to solve the problem involved naval architects have been met by some altogether novel problems. One of these is the arrangement of riveting, and with this feature the author dealt at some length, going into details in the thorough manner which his unique position enabled him to do. Without diagrams it would be impossible to follow the author in his various lines of reasoning, more especially in the matter of arrangement of tanks, the disposition of stringers, brackets, and other parts of a ship's structure. We will therefore refer those of our readers interested in this matter to the Transactions of the Institution for details, which were fully set forth by the author.

Dr. Elgar's paper was largely of an historical nature. The author, who was until lately the Director of Dockyards, is now the chief technical and scientific adviser to the Fairfield Shipbuilding Company of Glasgow, the largest shipbuilding corporation in the world. This firm has recently constructed the Atlantic liners *Campania* and *Lucania*, at present the biggest ships afloat. The paper drew a comparison between the *Great Eastern* and these modern vessels, which more nearly approach in size the monster ship of nearly forty years ago than any vessels ever constructed. The following table is interesting as drawing a comparison between the past and present :—

	Great Eastern.	*Campania.*
	ft. in.	ft. in.
Length over all	692 0	622 0
Breadth moulded	82 2	65 0
Depth moulded to upper deck	58 0	41 6
Load draught	30 0	27 0
Indicated horse power ...	8,000	30,000
Gross register tonnage ...	18,915 tons	12,950 tons
	Knots.	Knots.
Speed at sea (full power) ...	14 to 14½	22 to 23

These figures show at once the advance in marine science and the extent to which the past naval architects more than anticipated the work we have yet done in the size of ships built ; and it must be confessed the honours appear to rest with the engineer. The *Great Eastern* was fitted with both screw and paddle wheels, an arrangement which proved a costly mistake. It should be said, however, that the marine engineer has an almost unlimited field for the exercise of his ingenuity, whilst the naval architect is fettered and bound in the most vital element of design, namely, the draught of water. It is useless to build a ship which can never enter the great ports of the world, and here we have reached a limit of 27 feet. The ship designer waits for the civil engineer to improve the chief harbours of nations before he can exercise to the full the resources which modern science has otherwise placed at his disposal. An addition of another 5 feet to the depth of some of the chief commercial ports would mean an advance in ship construction before which the growth of the last twenty years, great as it is, would be far eclipsed. For this reason it is likely that the bulk of the *Great Eastern* will be unapproached for very many years. Her length, great as it was, was a smaller proportion to her breadth than in modern ships, and to equal her displacement on the proportions of beam and length which are now considered desirable, a modern ship would require to be considerably longer than was the wonderful craft which was the embodiment of such high ambition forty years ago, and which found her most profitable employment in her last days as a show for trippers to the Liverpool exhibition.

Mr. Ellis described in his paper trials made at the steel works of John Brown and Co., of Sheffield, to show the advantage of a combination of features which the author considers desirable in the generation of steam. He uses induced draught, heating of the air supplied for combustion, and Serve boiler tubes. We have never been able to see what ground the supporters of induced draught have for claiming the great virtues supposed to exist in drawing the air through the furnace by means of a fan in the chimney, rather than driving it through by a fan in the stokehole. It is easier to grasp the advantages of heating the air supplied for combustion, supposing it is done by heat that would otherwise be wasted, but it is an open question whether this regenerative process could not be beneficially replaced by heating the feed water to be supplied to the boiler. It is certain that heat from the waste gases or products of combustion will be more readily absorbed by water than by air. In regard to the part of the system involved in the use of Serve tubes, there is perhaps less room for doubt as to the advantages to be reaped. The Serve tube may be described as an ordinary boiler tube, having on its interior a number of metal ribs which are formed in one with the tube itself. The object of these is to penetrate the stream of hot gases, often flame, passing from the furnace to the chimney, and thus act as collectors for the heat to be transferred ultimately to the water in the boiler. The principle may be described as that of the Constantine stove inverted. The device appears logical and we can accept the statement that whatever heat is taken up by the metal is readily transferred to water surrounding the tubes ; or, as one speaker during the discussion put the matter, "if we look after the absorbing surface, we know the distributing surface will look after itself." That is true so long as the distributing surface is clean, but it is to be feared such a desirable state of things is not often present in steam boilers. Later in the meeting Mr. Blechynden, in his paper, pointed out how even wiping a plate surface with greasy waste on the water side caused the rate of transmission of heat to fall off, and Mr. Durston some months back told us how bad is the inner side of tubes and plates in a marine boiler. However, the Serve tubes appear to have made a favourable impression upon engineers in spite of the difficulties in the way of sweeping, &c., which threatened them at first. The problem of their introduction appears largely to have established itself on a commercial basis. In the tables attached to his paper Mr. Ellis gave details of the trials made. From 10¼ to 10½ lbs. of water were evaporated per lb. of coal from and at 212° Fahr., burning 40 to 45 lbs. of coal per square foot of grate per hour. The temperature of the gases in the smoke box was from 653 to 692° Fahr., whilst after passing through the apparatus used for transferring the heat of the gases to the air supplied for combustion the chimney gases, 386 to 391° Fahr., the difference between the two representing the arrestation of heat units by the regenerative apparatus, less accidental loss. An analysis of the chimney gases would form a valuable addition to these details, as was pointed out at the meeting. In any case, however, the boiler tested had a much better chance at Messrs. Brown's works than it would have had on ship-board ; nevertheless, the results may be said to be encouraging.

Mr. Hamilton's paper on wear and tear in water-ballast tanks was of a very special character, although a most important matter to shipowners. The moral of his investigations may be summed up in keeping boilers well off the bottom, filling tanks right up, and applying good paint properly at sufficient intervals. If it could be managed to thoroughly dry the tanks when empty it would be of more importance than anything else, but it is difficult to see how this is to be done.

Mr. Blechynden's paper was also of a special character, and gave the results of some very pretty experiments made to determine the problem referred to in the title of his paper. It would be difficult, without illustrations, to describe the experiments, but the broad general fact brought to light was, as the author stated, "that the units of heat transmitted through any of the plates per degree of temperature between the fire and water are proportional to the difference." The inference might be also drawn from the results that the steel plates lowest in carbon were also lowest in conductivity ; but the experiments, as the author said, should be extended to confirm this.

Mr. Milton's paper on water-tube boilers dealt with the subject of the hour, at any rate from a marine engineer's point of view. The paper described the most prominent types of water-tube boiler now on trial before the engineering world. By the triple and quadruple compound engine we have placed the motor so far ahead of the steam generators that marine engineers must perforce turn their attention to the first source of power on board ship. The introduction of corrugated furnaces gave the boiler a considerable step in advance, and, together with the use of steel as a material for construction, made the advances in marine engineering so well illustrated by Dr. Elgar's comparison of the *Great Eastern* and *Compania*, at all possible. Leaky tubes, however, have set us all back again, and the conviction is growing among engineers that an entirely new departure is required in boiler design. The only thing that offers is the water-tube system, in which steam is generated in a series of pipes containing water and surrounded by hot gases, rather than in a cylindrical shell through which tubes run to convey the products of combustion through their interior from the furnace to the chimney. The water-tube boiler is almost as old as the more ordinary multi-tube (fire-tube) boiler ; but unhappily the lamentable failures of a generation ago—in which several lives were lost—threw such discredit on the system that it has been tabooed ever since. We are now beginning to see how to get over the errors of the past, and the great feature now to be solved is the question of durability. That can only be settled by time ; and it seems possible that the water-tube boiler may creep from smaller to larger vessels until the shell boiler becomes a thing of the past on shipboard ; at least that is the opinion of some marine engineers whose word is entitled to the highest respect. Possibly in the meantime a practical way may be found of generating power in the motor itself without the intervention of steam and the apparatus for generating it. Before that time arrives, and some form of gas engine (including oil engines) arrive, a distinctly new departure will have to be made equivalent to that of the separate condenser of Watt.

The last paper in the list, that of Mr. G. H. Bryan on bulkheads, was in some respects the most promising and most suggestive of the meeting. The bulkhead question has been troubling the most thoughtful of our naval architects for some time past. Dr. Elgar attacked the question some time back in a paper he read before the Institution, and Mr. Martell also read a memoir on the subject. Some time ago a strong Government committee was appointed to consider the problems involved in this matter, and a report was issued. Rightly or wrongly, some naval architects are not satisfied with the position in which the report left the question. It is considered by many of the more thoughtful that a more scientific method of dealing with the problem should be evolved. Mr. Bryan, who is a Cambridge mathematician of high reputation at his University, has been led to take the matter up, and the present paper is an effort to bring higher mathematics to the aid of the solution of the question. The paper, however, contains nothing that need appal any naval architect or engineer who can lay fair claim to the title, and it is eminently practical. The similes selected by the author are of the simplest nature; indeed, the memoir reads more like a contribution from the pen of the late Mr. Froude, who was a very prince of lucidity and simplicity. We are reluctantly obliged, through want of space, to treat this paper as we have the others read at this meeting, and only give a suggestion of its scope, referring our readers to the Transactions of the Institution for fuller details. Mr. Bryan attacks the theory, still held by many engineers, that the plate may be regarded as consisting of a series of parallel strips supporting pressure by their tensions. Euler's and Bernouilli's early theories have been abandoned by mathematicians, and Mr. Bryan is now trying to persuade engineers to do the same in effect in giving up the "parallel strip" illustration. The matter affords an excellent example of the manner in which the student of higher mathematics may assist the engineer. We may add that it is proposed to discuss the subject at the next meeting of the Institution to be held next spring, and doubtless Mr. Holmes, the secretary of the Institution, would forward a copy of the paper to any one wishing to take part in the discussion. The address of the Institution is 5, Adelphi Terrace, Strand.

SOCIETY OF CHEMICAL INDUSTRY.

THE Annual General Meeting of the Society of Chemical Industry was opened at University College, Liverpool, on July 12, when Sir John Evans, K.C.B., Treas. R.S., delivered his Presidential address as follows:—

"When I look at the list of those who in past years have occupied the Presidential chair of this Society, all of them men eminent in the departments of either theoretical or practical chemistry, or, indeed, of both, I cannot but feel my own insufficiency to succeed them in worthily fulfilling the duties of this post. I am, indeed, tempted to inquire how and why it was, that, in accordance with the pressing invitation of some members of the Council, I ever consented to allow myself to be placed in nomination as your President. It certainly was not on the grounds of any fancied chemical attainments; nor was it from my having been in former years associated with any industry that is usually regarded as being specially connected with chemistry. Far less was it in the hope that any remarks that I might be called upon to make while acting as your President could be of any particular interest or value to those who, in all probability, are far better acquainted than I can pretend to be with any subject that properly comes within the scope of such a Society as ours. I believe, however, that the main reason that I had for allowing myself to be brought forward is one that will, to a great extent, palliate my shortcomings in so many of the essential requisites for such an office. It was the hearty and entire appreciation that I felt of the work and aims of such a Society as that of Chemical Industry, that was the prime mover in the case. Whether I regarded the organisation of the Society, with its sections at all the principal centres of chemical operations, each to a certain extent independent, but all working harmoniously together, and forming one powerful and important body, with high objects and aspirations before it; or whether I looked at it as presenting a bond of union between industries apparently unconnected, while, at the same time, furnishing information of the most useful character to each and all, I could not but recognise it as a body in the highest degree conducive to the public welfare; so that on these, if on no other grounds, I should have been wanting in public spirit had I stood aloof when others urged me to accept the post of your President.

"It is, I firmly believe, only by some such cordial co-operation among the different industries of this country as that which our Society has inaugurated, that the commercial position of Great, or Greater, Britain is to be maintained; and the more fully the interdependence between one branch of manufacture and another is recognised and acted upon, the more likely are we, as a whole, to maintain our place in the keen race of competition with other countries.

"A merely cursory glance at our Journal will at once show how numerous are the departments of British industry that are more or less dependent on chemical knowledge, the information given on current literature and the specifications of new patents being arranged under no less than three-and-twenty different heads, many of them embracing several varying occupations. Not a few of these headings would, within my own memory, have conveyed but little meaning even to experts. I need merely carry back the minds of some of the elder members of the Society, not only to the days when aniline colours were not and Dr. Perkins was comparatively unknown, but to the time when lucifer matches had not been invented, when photography was practically non-existent, and when in most of those industries in which a knowledge of chemistry is now regarded as indispensable, the 'rule of thumb' reigned absolute.

"I can speak of those old times with some personal feeling, as it is now upwards of fifty years since, that having presumably completed my education, I first entered a paper-mill in order to learn the art and mystery of the manufacture of paper, with which the name of the firm of which I was until lately a member—that of John Dickinson and Co.—has been so long, and, I may venture to say, so honourably connected. It was, of course, recognised that some knowledge of chemistry was a requisite in such a manufacture, but I must freely confess that our methods were of the rudest, and that it was only as years rolled on, and first esparto fibre, and then the different kinds of wood pulp were introduced into the manufacture, and the various methods and results of sizing studied, that a thorough acquaintance with chemical laws became a *sine qua non* for those who hoped for success in this branch of industry.

"At the date that I have in view—say 1840—although rags were the staple material for the manufacture of paper, our consumption of them was but small, and they were principally used by us in producing paper for copper-plate work—steel plates at that time being rarely used—and for the highest class of printing papers. We consumed, however, a large quantity of raw material in the shape of the waste arising in the manufacture of linen and cotton goods, and we had collecting agents at Dundee, Belfast, Bradford, Leeds, and Manchester, who bought the waste upon the spot. At Manchester we had a mill, in which the cotton-waste was cleaned, boiled, and converted into what is known as 'half-stuff,' which was finally bleached and made into paper at our Hertfordshire mills. In that county we had another 'half-stuff' mill, at Rickmansworth, where the linen waste was treated. The boiling was carried on in open keirs, or such as were partially closed, and always at a low pressure, as high pressure boilers for such materials were practically unknown. Most of the waste was twice boiled, first with caustic lime, and secondly with a small amount of soda. The 'shieves,' or woody particles, that were unreduced by the boiling, were got rid of by a long process of screening, or 'devilling,' after the 'half-stuff' had been dried so far as possible in hydraulic presses. The material was then bleached in stone chambers by the direct action of chlorine gas, produced on the spot in retorts. At the mills, however, where the 'half-stuff' was converted into paper, the remains of the chlorine had to be washed out, and the final bleaching of the stuff to be effected with bleaching salts. No process for the recovery of the soda used in boiling was then known, and, indeed, the quantity used was so much less than that which is now necessary with esparto, that it would not have paid to recover it. I remember, however, being engaged in some experiments for the recovery of the manganese from the spent liquor of the retorts. Even when first Mr. Routledge introduced the use of esparto fibre no evaporating or recovery process was employed, but the double advantage was soon seen of avoiding the nuisance of polluting the streams into which the waste liquors were allowed to flow, and of regaining a quantity of soda at a small cost. With the general adoption of esparto as a material a radical change in the manufacture of paper was effected, and the difficulties in which the industry had been placed by reckless commercial legislation with regard to foreign rags in a great degree removed.

"What has taken place in the manufacture of paper has been paralleled in numerous other departments of commercial enterprise, and not the least in those connected with the manufacture of chemical products themselves, in many, if not indeed in most of which a complete revolution has been effected within the last fifty years, or even less. It would be a hopeless task to try to indicate the whole of the advances in chemical knowledge that have been made within that period, and yet I am tempted to give some few reminiscences of the condition of the science as exhibited in *Brande's Elements of Chemistry*, published in May, 1841, exactly twelve months after my first introduction to business, when compared with our knowledge at the present day.

"Chemistry at that time was by no means in its infancy. Its foundations had been securely laid not only on the Continent, but in this country, and the names of Priestley, Cavendish, Scheele, Lavoisier, Davy, Wollaston, and other English investigators were already household words. There were, in 1841, twelve simple non-metallic substances known, from oxygen to boron, including selenium, and forty-three metals from potassium to silicium, including lantanum and thorinum. For all fifty-five, symbols had been arranged, but these were in many respects different from those which are now in universal use. C, for instance, stood for chlorine and not for carbon, while B symbolised bromine and not boron. Potassium was designated by Po and not by K, and sodium by So and not by Na, while uranium was known as Urnm and not as U.

"The atomic weights of the various substances had been approximately determined, though modern investigations have in some instances materially changed their ratio. Though hydrogen has retained its place as the unit, oxygen is no longer represented by 8, but by 15·96, or even less. Sulphur that was then 16 is now 31·98. Selenium, instead of 40, has now 78 assigned to it; while the number for tellurium has been increased fourfold from 32 to 128, and phosphorus has gone up from 16 to 30·96. Whether all our present figures will stand the test of time remains to be seen, and indeed recent researches have shown cause to doubt the accuracy of some of the figures that I have quoted. For myself, as a somewhat profane outsider, I must confess that it would be a source of satisfaction if future investigations should show that the figures now having three or four places of decimals attached to them might more properly be converted into integers, and oxygen came out boldly as 16, and sulphur as 32. This is, however, a digression.

"Turning to the simple substances and metals of which, as already stated, 12 and 43 respectively were known in 1841, we find them now slightly increased. Of non-metals we reckon 15, and of metals 48. Some metals, like columbium and glucinum, have dropped out of our list, the latter having now become beryllium, while others, like cæsium, didymium, erbium and rubidium, have come in.

"On the whole, the changes and advances in inorganic chemistry have not been extreme. It is in organic chemistry that what cannot be regarded as anything short of a revolution has taken place. It is not a matter on which I can dilate, but as indicative of what has been going on I may mention that while three volumes have sufficed to Roscoe and Scholemmer for inorganic chemistry, no less than six have already appeared in continuation treating of organic chemistry, and more are to follow; so that the proportions have been reversed which prevailed in the days of Brande, who devoted 367 pages only to organic chemistry, and 1042 to introductory matter and inorganic chemistry.

"But whatever may have been the advances in chemistry within the last fifty years, whether as a pure or an applied science, the extension of its boundaries towards physics in the one direction, and biological studies in the other, is at least as remarkable. While the study of spectrum analysis has rendered most valuable assistance in the chemistry of the constituent substances with which we are familiar upon earth, it has enabled the astronomer to carry his speculations not only to the constitution of the sun and stars, but to that of nebulæ, comets and meteors, and in the hands of Mr. Norman Lockyer and Mr. Huggins may yet lead us to travel with some degree of confidence in paths hitherto untrodden. In the domain of electricity it is hard to say whether that science does not owe nearly as much to chemistry as chemistry does to it. In the practical application of electricity to lighting purposes, chemistry has still to be called on to produce some improved form of secondary battery, and some portable form of primary battery which shall prove of ready application by our miners. It is needless to recall how much our underground workers are indebted to chemistry for their comparative immunity from danger from fire-damp, a danger which the efforts now being made by chemists will, I hope, still further diminish. Electricity has also placed at the command of chemists greater intensity of heat than can be derived from ordinary sources.

"The study of heat, irrespective of electricity, has largely reacted on chemistry, and while the Bessemer process has entirely revolutionised the manufacture of steel, and almost annihilated the distinction in value between that and other forms of iron, the Siemens and other furnaces have led to unprecedented economies in the expenditure of fuel, and at the same time have facilitated the application of heat in various chemical processes. In the other direction—the absence of heat—Prof. Dewar has, during the present year, made most important advances. Although air had previously been liquefied, he has now been able, by means of intense cold alone, to reduce atmospheric air to the liquid condition. His further results, by a combination of enormous pressure and extreme cold, are well known, and now that oxygen and nitrogen have yielded themselves to the advances of science and have been obtained in quantities in a liquid state, it is hard to say that hydrogen is destined always to remain intractable. What may be the ultimate result of the investigations that can now be carried on at temperatures ranging from 100° to 200° centigrade below the freezing point of water, it is impossible to foresee. From researches already made in this country and in France, it would appear that most substances under extreme cold are, so to speak, dead, and that their ordinary affinities are in abeyance. Possibly what may be termed 'glacial chemistry' may eventually enlarge our views as to the various properties of matter.

"As to the advances in our knowledge of the chemistry of light, the present condition of photography may testify. When we can take the image of a bullet flying at the rate of 3,000 feet per second, with its accompanying cone of compressed air; when we can produce photographs which are practically permanent, and when we call in the action of light to engrave our steel or copper plates, and to produce efficient substitutes for woodcuts, we seem to be getting near the limits of the practical application of photography. And yet many of us may remember the days when the daguerrotype was regarded—and justly so—with wonder; and I can myself call to mind a still earlier form of photography, by which natural leaves were reproduced on paper sensitised with a salt of silver, of which I saw specimens in an exhibition at Dresden so long ago as the year 1839.

"In the introduction of artificial light much also has been done. It is true that Pall Mall was experimentally lighted by gas in 1807, but it was not until 1842 that gas found its way into Grosvenor-square and some other aristocratic quarters of the metropolis. Since that time immense strides have been made in the process of gas manufacture, while, in consequence of the waste products arising in the process having now found commercial uses, great reductions have been made in its cost. At the present time gas has to compete with electricity as an illuminant, while, in many cases, it has been superseded by mineral oils, which are now so abundant and cheap, and of which in this Society the flashing point may be said to be almost a burning question. If, however, gas is losing ground as an illuminant, it seems to be gaining it as a source of power, and there are prospects of a considerable increase in the use for this purpose of hydrogen and its compounds, containing far less carbon than ordinary coal-gas.

"In metallurgy also, in addition to the improvements in the manufacture of steel already mentioned, many noteworthy discoveries have been made. One of the most important of these is perhaps that of the production of aluminium on a cheap scale and in quantities sufficient for various applications to ordinary use. It seems somewhat remarkable that the progress in the use of a metal at once so light and so strong is not more rapid.

"The applications of some of the more modern alloys, such as phosphor-bronze, seem also susceptible of considerable further development.

"The extensive manufacture of sodium affords another instance of what was formerly the mere subject of a laboratory experiment, being now conducted upon a commercial scale.

"I may here just glance at the attempts that have been made to produce artificially some of the precious stones that occur in nature. Rubies have been manufactured, not indeed such as could rank as gems, but still such as will serve to 'jewel' the pivot-holes in watches; and though the results of attempts to produce the crystallised form of carbon, which is known as the diamond, have as yet had but doubtful success, it does not appear to me that the prospect of producing genuine diamonds under combined heat and pressure is absolutely hopeless.

"Another direction in which great advances have been made, and in which it seems probable that there yet remains something to be discovered, is the grouping of the various elements into small divisions, having more or less analogy the one with the other, and the classification of the atomic weights in one harmonious series. What is known as the Periodic Law of Mendeleeff and of our own Mr. John A. R. Newlands, has suggested the possibility that what we now know as metals or elements may have some at present hidden connections between them, so that eventually some of them may prove to be rather compound bodies than strictly elementary substances. This, however, is for the chemistry of the future.

"In organic chemistry, which has been defined to be the chemistry of the hydro-carbons and their derivatives, it is, as I have already observed, that the most wonderful development has taken place within the last half-century. Who, for instance, in 1840 could have foreseen the important part that aniline was to play in dyeing and colouring? It was not, I think, till 1856 that Perkins's mauve was really brought into commercial use, but since that time what a rainbow of colours has been produced from what would have seemed a most unpromising source! How brilliant are their hues, but as yet, in many cases, alas, how fugitive! Regarded from an artistic point of view these colours can hardly be esteemed an unmixed blessing; and even the fabrics of Eastern looms have not escaped their influence.

"Quæ regio in terris nostri non plena *coloris?*"

Turkey, Persia, India, and China have, I fear, in many cases, sacrificed taste to cheapness, and harmony to splendour in colour. It is a source of some satisfaction to know that the woad with which our ancient British predecessors stained their bodies is still cultivated among us for the purpose of dyeing wools, even though it has acquired the name of *Isatis tinctoria* and the colouring extract is now classed as an *Indigotin*.

"Among inorganic colours I may here briefly mention ultramarine, which instead of being patiently produced by the careful treatment of lapis lazuli and sold at many shillings an ounce, is now manufactured by the ton and quoted by the hundredweight. Would that the artificial colour was as fine and permanent as the natural! I have, in my own time, seen it supersede smalts as a colouring matter in paper-making, and I have known its use not unfrequently accompanied by the abundant presence of sulphuretted hydrogen as a product of its decomposition.

"Not only colouring matters but our flavours and scents have been synthetised, though art, if superseding nature for a time, must eventually acknowledge her inferiority even in pear-drops. Whatever our æsthetic feelings under these circumstances may be, we cannot but admire the skill and scientific energy by which such results have been attained. How far 'saccharine,' one of the lastest results of the chemist's ingenuity, is likely to supersede the use of ordinary sugar, is a question on which I decline to speculate. The manufacture of our every-day sugar has, however, itself undergone a complete metamorphosis within the last fifty years, with the result that it is now produced at what would formerly have been regarded as an absolutely impossible price. In 1840, beet-sugar was in its infancy, and such has been the improvement in the growth of the beet and the process of manufacture that nearly twice the weight of sugar is now produced from a ton of beetroot as there was at that date. In the production of cane-sugar also immense economies have been effected, especially in the process of evaporation. The study of the effects of saccharine solutions on the polarisation of light, and our acquaintance with the distinctions between dextrose and lævulose, and of the conversion of starch into sugar, all come within comparatively modern times.

"Much of our knowledge of the mysterious processes of fermentation is also of recent date, and it is in connection with these processes that the chemist finds himself brought into close contact with the botanist and the physiologist.

"Whatever suspicions Leeuwenhoek and the early microscopists may have had with regard to the vegetable character of yeast-cells, and however clearly Cagniard de Latour and Schwann may have established its plant-like nature and its connection with fermentation, it was not until Pasteur's researches from 1857 to 1861 that the true character of the yeast-plant, and of other micro-organisms which lie at the base of most fermentative processes, can be said to have been absolutely demonstrated. The beneficial effect of his inquiries, and of his methods of obtaining a pure cultivation of yeast, is universally recognised, and has reacted in the most remarkable manner on the brewing industry.

"But M. Pasteur's researches have also led to much wider results, as it has been mainly in consequence of his careful observations that the wonderful influence for good or for evil of organisms so minute as in some cases almost to defy the power of the microscope, has now been so fully recognised. The germ-theory of the origin of many diseases meets with much more general acceptance than it did but a few years ago; and though the bacilli and bacteria which are characteristic of some virulent diseases, such as anthrax, are only agents in certain fermentative processes by which poisonous matters are engendered, their existence and character seem to be placed beyond all doubt. The process of obtaining immunity from the action of these poisons by the gradual introduction of the virus into the animal system, thus rendering it insusceptible of receiving further injury from the same poison, has been successfully introduced, both among men and beasts, and hydrophobia and anthrax have been successfully combated.

"A recognition of the influence of germs has led to the introduction into surgery of that antiseptic system of treatment with which the name of Lister will always be associated, and which has done so much to diminish suffering and preserve life. While upon this topic I may just allude to another instance in which chemistry has come to the assistance of medical science, I mean in the production and investigation of those anæsthetic agents which play so important a part in modern surgery, and which have done so much to alleviate human suffering.

"But while the ferments produced by micro-organisms are on the one hand so pernicious, it is very doubtful whether, on the other, they are not equally beneficial, if it be really the case that such processes as digestion are in a great measure due to their action. How far the nitrification of the soil may be due to micro-organisms is a question not yet absolutely solved, though strong presumption has been raised of their being, at all events, potent factors in the case.

"Now that so many diseases have been traced to pathogenic organisms which are constantly present in water contaminated by sewage, the question of the vitality of these organisms and their germs has been rightly regarded as one of great public importance, and the Royal Society, in conjunction with the London County Council, has instituted an investigation into it, which is being diligently prosecuted both from the botanical and the chemical points of view. The remarkable power of light, whether that of the sun or electric, in sterilising the germs of some micro-organisms, already to some extent previously known, has been conclusively demonstrated by Prof. Marshall Ward.

"Much has been done of late years by chemists towards the purification of sewage with the view of rendering the effluents from the ultimate drains of our large municipalities as innocuous as possible, and the results obtained have been in many instances satisfactory. They would, no doubt, have been even more so had not the imperative demands of economy limited the cost. Still, whatever may be done, I am inclined to think that there is much truth in the metrical abstract of a paper read some years ago before the Royal Society:—

"Sewage, however disinfected,
Is not from ill results protected;
Though made to all appearance pure,
It still remains not safe, but sewer."

"I will not attempt to discuss the important question of the disposal of the sewage of our great towns, but to many it will appear as somewhat of a disgrace to our powers of applying chemical knowledge, that such vast accumulations of what were originally highly fertilising substances should be discharged into the estuary of the Thames, and not only be absolutely wasted, but converted into a perpetual nuisance, brought up at each tide within the limits of the metropolis from which they started.

"It is true that within the last fifty years we have imported enormous quantities of guano, phosphates, and nitrates, but of these there must eventually become a scarcity, if not an end. In the meantime, may not chemists do something to reduce the waste of fertilising agents that is now taking place among us? Agricultural colleges have been founded—agricultural chemistry is a recognised branch of science; but with increase of knowledge has come increase of foreign competition, fostered by improved means of transport and communication, and it is at the present time a doubtful point whether many soils, even if rent-free, can be cultivated in this country for cereals, except at a loss.

"While touching on agricultural chemistry, I cannot pass over in silence the experiments which have now been carried on continuously for a period of fifty years at Rothamsted, by Sir John B. Lawes, assisted during the whole half-century by Dr. Gilbert. The extremely liberal provision which, during his life-time, Sir John Lawes has made for the purpose of continuing and extending his experiments, would alone entitle him to a full measure of public gratitude. When, however, we consider the nature and extent of the experiments already conducted, we must feel that no expression of public estimation can be too high when, as will shortly be the case, the Rothamsted jubilee is celebrated. As to the results already obtained, and as to the nature of the experiments still being carried on, it would be out of place here to enlarge. Remarkable, however, as are the effects of different manures on the botanical character and growth of herbage, and on the strength and yield of cereals, the different results arising from the mere variation of the temperature, sunshine, and rainfall, in successive years, are more remarkable still.

"I feel, however, that I have detained you long enough with these crude considerations of topics more or less chemical in their character, and that it is time for me to conclude.

"We are here assembled on the borders of the two counties of Lancashire and Cheshire, in both of which are great centres of chemical manufactures, and the principal productions of which are in a great degree dependent on the knowledge and due application of chemical laws. We meet at the seat of one of the most active sections of the Society of Chemical Industry, which has received us with open arms, and has provided us with an 'Open Sesame,' which will admit us to inspect many of the most interesting of the works and factories of the district. We gladly avail ourselves of the opportunities thus liberally opened to us, and if by chance any of us can afford assistance, advice, or encouragement to our brethren in Liverpool, I am sure that all present will gladly render it, and not forget that we are all members of one body, and all mutually interested in the advance of chemical knowledge, and especially of Chemical Industry."

THE PLAGUE OF FIELD VOLES.

RATHER more than a year ago a Committee was appointed by the Board of Agriculture to inquire into and report upon the circumstances attending the existing plague of voles in some of the southern counties of Scotland; and to ascertain, either experimentally or otherwise, whether any, and if so what, preventive and remedial measures could be adopted, and under what conditions those measures were likely to be of value.

The committee consisted of Sir Herbert Eustace Maxwell, Bart., M.P. (chairman), the Right Hon. the Earl of Minto, K.T., the Rev. John Gillespie, Prof. D'Arcy W. Thompson, and Mr. Walter Elliot.

Mr. J. E. Harting, Librarian of the Linnean Society, acted as the Secretary to the Committee.

From the recently-published report we obtain the following information. "The animal, which by excessive multiplication has caused so much mischief on hill-farms in the southern uplands of Scotland, is the short-tailed field-vole (*Arvicola agrestis*). At all seasons it is a well-known inhabitant of our pastures and may be found at all heights from sea-level to near the summits of our highest mountains. It usually produces three or four litters a year, each consisting of from four to eight young, but in some seasons they are even more prolific, the breeding season is prolonged, young voles being observed from February to November, and the litters containing as many as ten young.

"The present outbreak may be traced back to the year 1888, when the voles were observed to be increasing on the farm of Glenkerry and others in Selkirkshire. In the summer of 1889 the low-lying pastures near Closeburn, in Dumfriesshire, were observed to be infested by enormous numbers of voles, which remained there during 1890, and disappeared in 1891, probably moving up to the hill pastures, where in June 1892 they were swarming.

"The districts principally affected are the hill pastures in the north-west of Roxburghshire, the south of the counties of Selkirk, Peebles, and Lanark, and the northern part of Dumfries from Eskdalemuir by Moffat to Thornhill. The voles have also appeared in great numbers in the parishes of Dalry and Carsphairn, in the stewartry of Kirkcudbright.

"Mr. R. F. Dudgeon has estimated that in Roxburghshire 30,000 to 40,000 acres had been affected, of which he considered 12,000 to 15,000 acres had been rendered useless; in Dumfriesshire 40,000 to 50,000 acres, and in the stewartry of Kirkcudbright 10,000 to 12,000 acres were described by him as infested by voles."

"The map accompanying the report of the Committee shows that an area not less than 600 miles in length and from 12 to 20 miles in breadth has been overrun.

We reprint the following conclusions and recommendations contained in the report.

"The Committee have reluctantly been led to the conclusion that they are unable to recommend any specific method of dealing with or putting an end to the present outbreak.

"It appears to be an instance of the power which small animals are well known to possess, of prodigiously rapid multiplication under favourable climatic conditions and with a plentiful supply of natural food.

"Experience shows that a combination of such favourable conditions will always tend to bring about a recurrence of the plague. That being so, it ought to be the endeavour of every farmer and shepherd to be on the alert, and report without delay to the land agent, and to the secretary of the local farmers' club, or agricultural society, the first signs of the multiplication of vermin, so that palliative measures may at once be adopted, not on isolated farms, but everywhere throughout the district.

"The most effective measures appear to be periodical and timely burning of grass and heather, followed by active pursuit of the vermin by men using wooden spades and dogs. If this were promptly done in the early stages of the outbreak, it is quite possible that it might be averted altogether, or greatly mitigated in severity.

"It is hardly necessary to point out that the proprietor of the land should be informed as soon as anyone else, because his keepers and others might be usefully employed in assisting to prevent what amounts, if unchecked, to a common calamity upon all classes connected with land.

"Where plantations of limited extent are attacked, pit-falls wider at the bottom than at the top and about 18 inches deep should be dug. The voles fall into them and cannot escape, and the ground is soon cleared of them in this way.

"The Committee cannot speak with approval of the use of poisoned grain, except where the area affected is very limited.

"Nor have they been able to come to any conclusion favourable to the adoption of Prof. Loeffler's method of destroying voles by means of bread saturated in a preparation of the *bacillus typhi murium*, or mouse typhus. The personal investigations made by the chairman and secretary in Thessaly (where in May 1892 Prof. Loeffler was employed at the expense of the Greek Government to combat the plague of field-voles then prevailing in that country) convinced them that the favourable reports circulated as to the complete success of the experiments have not been justified by the results. In certain parts of Thessaly the voles were reported by landowners and others to be as numerous in January 1893 as ever they were.

"The Committee readily admit that, when used in a fresh state, the bacilliferous fluid is an effective though somewhat dilatory poison for mice and voles, and has this advantage over mineral poisons that, as has been proved, it is innocuous to human and other forms of life.

"It has also been reported by Prof. Loeffler that the Scottish voles sent to him alive by instructions from the Committee have been found as susceptible of the mouse typhus bacillus as their

Greek congeners. But there are three objections which render this method almost worthless except for employment in houses, gardens, enclosed fields, or other limited areas:—

"(1) It is very expensive; the virus supplied to the Greek Government was paid for at the rate of 4s. a tube, containing enough when dissolved to treat about two imperial acres, a cost which in many instances would exceed the rent of the Scottish hill pasture. To this must be added the price of bread used in distributing the virus, which would appreciably raise the cost of the process. Thus to deal effectually with a hill farm of say 6000 acres, would entail an expenditure of from £700 to £1000, making the remedy more costly than the evil.

"(2) Mouse typhus is not contagious; it can only be communicated to those animals that will swallow some of the virus. The allegation that healthy voles will become infected by devouring the bodies of the dead has not been satisfactorily proved. That Greek voles when in captivity have been observed to feed upon the corpses of their fellows hardly warrants the assumption that Scottish voles in a state of liberty will do the same; and unless the disease were communicable from one animal to the other, it is not easy to see how the remedy could prove effective on extensive hill pastures.

"(3) The fluid loses its value in about eight days after preparation. Consequently much disappointment might ensue if, after a supply had been obtained, a fall of snow or wet weather were to interfere with its distribution over the land.

"The remedy which has been found most effectual in Thessaly is an injection of the fumes of bi-sulphide of carbon into the burrows. This, however, is a more expensive process than the other, besides being injurious to the health of those engaged in its application. It is, moreover, inapplicable to the Scottish vole (*Arvicola agrestis*), which does not burrow to a depth like the vole of Thessaly (*Arvicola Güntheri*), but lives in shallow runs amongst the roots of herbage.

"With the under-noted exceptions the natural enemies of the voles may be divided into two classes, viz., those which destroy the voles, and are harmless to sheep, crops, and game; and those which, though preying on voles, are so hurtful in other ways as to have no claim to preservation:—

(i.) Vole-killers, harmless, or nearly so, to sheep, crops, and game.	(ii.) Vole-killers, hurtful in other ways.
Owls of all sorts,	Foxes,
Buzzards,	Ravens,
Kestrels,	Carrion and Hooded Crows,
and the smaller Seagulls.	Great Blackbacked Gulls,
	and Adders.

"Strict injunctions ought to be given by landowners that the birds mentioned in the first class should not be destroyed. Their presence in full numbers, though inadequate to avert an outbreak, would undoubtedly tend to mitigate it, and, as has been proved in the case of the short-eared owl, they have the faculty of multiplying a normally in presence of an unusual supply of food. They are at all events most useful allies to man in combating attacks of ground vermin.

"The Committee further deprecate in the strongest manner possible the use of the pole-trap for the capture of hawks. Besides the inhumanity of this device, it is indiscriminate, and harmless owls, kestrels, and buzzards are just as likely to be taken by it as are the more mischievous species.

"Three animals, diligent vole destroyers, have been omitted from both these lists, because they are undoubtedly hurtful to game. The first of these is the common rook (known to the shepherds as the corn crow), of which, however, the services to agriculture are now generally recognised.

"The other two animals referred to are the stoat and weasel. Of all the smaller beasts of prey these are perhaps the most hateful to gamekeepers, and it is hardly reasonable to expect that stoats should be allowed to multiply in game coverts, or in the vicinity of pheasant coops. But the Committee have no hesitation in recommending that weasels, which are persistent mouse-hunters and do little damage to game, should not be molested, at least on moorlands and hill pastures, where they can do little harm and much good."

THE ZOOLOGICAL SOCIETY.

THE report of the Council of the Zoological Society of London for the year 1892 was read at the annual general meeting on April 28, and printed copies of it were distributed shortly afterwards. The following extracts are of general interest.

"The considerations which prompted the Council of the Society, as announced in their report last year, to award two of its medals to the representatives of families through whose exertions the Great Skua has been retained as a veritable member of the British fauna, have induced the Council to act this year in like manner in regard to a still scarcer species—the osprey (*Pandion haliætus*). It has been represented to the Council that for some years past but three pairs of this bird, which on many accounts is of great interest, have regularly bred in Scotland, and that their protection has been an object of much solicitude to those on whose property the nests are built. The Council are able to state that the effect of their former award has not only been beneficial to the birds concerned, but has been highly appreciated by the public at large, and they trust that the same good result will follow the bestowal of the Society's silver medal upon Donald Cameron, of Lochiel, and John Peter Grant, of Rothiemurchus, in recognition of the efforts made to protect the osprey in their respective districts."

These medals were presented to the above-named gentlemen at the general meeting of the Society on June 22.

Reference was made to the resolutions adopted by the Council in regard to steps proposed to be taken by the Government of New Zealand for the preservation of the native birds of that country. The resolutions were as follows:—

"That the Council of this Society have learnt with great satisfaction the steps that were proposed to be taken by the Earl of Onslow, when Governor of New Zealand, and by the Houses of General Assembly, for the preservation of the native birds of New Zealand, by reserving certain small islands suitable for the purpose, and by affording the birds special protection on these islands.

"That the Council much regret to hear that difficulties have been encountered in carrying out this plan as regards one of these islands (Little Barrier Island), and trust that the Governor of New Zealand may be induced to take the necessary steps to overcome these difficulties, and to carry out this excellent scheme in its entirety.

"The Council venture to suggest that, besides the native birds to be protected in these reserves, shelter should also be afforded to the remarkable Saurian, the Tuatera lizard (*Sphenodon punctatus*), which is at present restricted to some small islands on the north coast of New Zealand in the Bay of Plenty.

"The number of visitors to the Society's gardens in 1892 was 605,718. The corresponding number in 1891 was 598,730, showing an increase of 6988 entrances.

"The deaths during the past year have been 862 in number, being 40 in excess of the number of deaths during 1891. Of these the more important were—a lioness, a male cheetah, two common zebras, an aard wolf, a male beatrix antelope, and the last surviving giraffe.

"Two gentlemen have utilised the students' rooms for carrying on investigations. Mr. F. G. Parsons has been studying the comparative myology of the rodents; and Mr. P. Chalmers Mitchell has commenced an investigation upon the spleen of the vertebrata.

"The number of animals belonging to the first three classes of vertebrates living in the Society's menagerie at the close of 1892 was 2413. The corresponding number on December 31, 1891, was 2232.

"The total number of registered additions to the menagerie in 1892 was 1335, of which 698 were acquired by presentation, 315 by purchase, 141 were bred in the gardens, 142 were received on deposit, and 39 obtained in exchange.

"Among the deaths of animals in 1892 occurs that of the last remaining individual of the stock of giraffes, a male, purchased January 27, 1879. The Society is now, for the first time since the arrival of the four original giraffes on May 24, 1836, without any representative of this mammal in its series. Nor does there seem to be at present much chance of our being able to supply the deficiency. Owing to the closure of the Soudan by the Mahdists the supplies of this and other large African mammals, which were formerly obtained *via* Cassala and Suakim, have ceased, and, so far as can be ascertained, there are now no living giraffes in the European market. There have been thirty individuals of the giraffe in the Society's gardens since 1836, of which seventeen were born there, and thirteen acquired by purchase. Of these thirty, one was presented to the Royal Zoological Society of Ireland in 1844, five have been sold at prices varying from £450 to £150, and the remainder have died in the gardens.

"In concluding their Report the Council express their regret that it has not been possible, during the past year, to continue their former policy of adding to the permanent structures in the gardens. There are still several buildings much wanted for the better housing of certain parts of the collection, amongst which may be specified the anthropoid apes and the struthious birds, for which groups special accommodation is required. But in both these cases, to carry out the plans efficiently, a considerable expenditure would be necessary, and the margin of receipts over expenses is at present too slender to render it prudent to undertake the work. The Council look forward to the time when the small remaining balance of the mortgage-debt upon the Society's freehold house will be paid off, and when there will be at any rate a better prospect of devoting the surplus income to such purposes."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE following is the list of scholarships and prizes just awarded at the Royal College of Science, London, with which is incorporated the Royal School of Mines:—First year's scholarships, Robert W. Forsyth, George W. Walker, John Thomas, Harry R. Prescott; second year's scholarships, Bernard E. Spencer, George S. West; "Edward Forbes" medal and prize of books for biology, Henry Lacey; "Murchison" medal and prize of books for geology, Joseph B. Morgan; "Tyndall" prize of books, for physics (Course I.), George D. Dunkerley; "De la Beche" medal for mining, Samuel W. Price; "Bessemer" medal and prize of books for metallurgy, Allan Gibb; "Frank Hatton" prize of books for chemistry, Robert E. Barnett. Prizes of books given by the Department of Science and Art: Mechanics, William H. Pretty; astronomical physics, William E. Tubbs, Willie Whalley; practical chemistry, Robert E. Barnett, Gerald G. Quinn; mining, Samuel W. Price; principles of agriculture, Robert S. Seton.

DR. BUTLER, Master of Trinity College, Dr. Hill, Master of Downing College, Dr. Peile, Master of Christ's College, Dr. Sidgwick, Knightbridge Professor, Dr. Jebb, Regius Professor of Greek, Dr. J. Ward, Dr. Keynes, Mr. F. E. Kitchener, Mr. R. T. Wright, and Mr. A. Berry will represent Cambridge University at a conference on the relations between the work of the Universities and the work of secondary education in England, to be held at Oxford on October 10 and 11, 1893.

MR. HENDRICK, of the Royal Agricultural College, Cirencester, has been appointed lecturer and demonstrator in agricultural chemistry by the Glasgow and West of Scotland Technical College.

PROF. W. GARNETT, M.A., D.C.L., Principal of the Durham College of Science, Newcastle-on-Tyne, has been appointed director and technical adviser to the Technical Education Board of the London County Council.

SCIENTIFIC SERIALS.

THE most important papers in the *Botanical Gazette* for April and May are an account of a newly-discovered fungus, *Phyllogaster saccatus*, by Mr. R. Thaxter, proposed as the type of a new family, *Phyllogastreæ*, characterised by the absence of any volva or receptacle differentiated as such in the mature condition; on the tendrils of *Passiflora cœrulea*, by Mr. D. T. McDougal, in which the author states that the tendrils of the passion-flower are sensitive to contact with one another, contrary to Darwin's experience with *Bryonia* and *Echinocystis*; on the limitation of the term "spore," by Prof. C. McMillan, which does not seem to throw much light on the confusion at present prevailing; the commencement of a paper, by Mr. G. F. Atkinson, on the biology of the organism which causes the root-tubercles in the *Leguminosæ*; and on the genus *Corallorhiza*, by Mr. M. B. Thomas, who finds in the cells of the cortical tissue hyphal threads which he regards as the agent by means of which the plant is able to derive nutriment saprophytically from the decaying vegetable matter around it.

IN the *Journal of Botany*, for May and June, in addition to the serial papers to which allusion has already been made, Mr. W. Phillips describes the rare fungus, *Gyromitra gigas*; Messrs. E. F. and W. R. Linton, in a paper on British hawkweeds, add four more to the already too numerous British species or subspecies of *Hieracium*, viz. *H. graniticolum*, *clovense*, *Boswelli*, and *stenophyes*; in an article on some marine algæ from New Zealand, Mr. R. J. Harvey Gibson describes and figures a new seaweed, *Rhodocorton Parkeri*.

Meteorologische Zeitschrift, June.—On the climatic effect of forests upon their neighbourhood, by E. Ebermayer. The discussion is based upon observations made in Austria since 1866, and the results arrived at are that forests do exert an influence on temperature and humidity, but not to the same extent as mountains and large lakes. Within the forest the daytime is naturally cooler and the nights warmer, while some of the effects are beneficial and others injurious to vegetation. The connection between forests and rainfall is not proved; in any case the effect on local distribution of rainfall is quite subordinate.—Earth temperatures at Hamburg, in the years 1886–91, by W. J. van Bebber. Monthly and extreme values are given at depths of half a metre, and for each metre up to five, together with the temperature of the air and of the surface of the Elbe. The average extreme annual variation, at a depth of 0·5 m. amounts to 30°·6 F., but at a depth of 5m. the variation falls to 8°·1. At the former depth extreme temperatures of 66° and 30° occasionally occur, while at the latter depth temperatures exceeding 52°, or less than 39°, are very seldom recorded.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 15.—"On *Megaladapis madagascariensis*, an extinct gigantic Lemuroid from Madagascar." By C. J. Forsyth Major, M.D., For. Corr. Zool. Soc. (Communicated by Dr. Henry Woodward, F.R.S., V.P.G.S., &c.).

It is now forty-two years since Isidore Geoffrey Ste.-Hilaire announced to the French Academy of Science the discovery of gigantic eggs and a few bones of *Æpyornis* from superficial deposits in the island of Madagascar, anticipating that a rich fauna of extinct vertebrata would be speedily forthcoming.

Little has, however, been added to our knowledge since 1851 until the present time. In addition to the remains of a Crocodile, two Chelonians, and a *Hippopotamus*, first discovered by Grandidier, the number of distinct forms of *Æpyornis* is now rapidly increasing, and promises to rival in variety the New Zealand species of *Dinornis*, whilst the disclosure of a rich mammalian fauna seems only waiting to reward the carrying out of systematic exploration.

Four collections of sub-fossil vertebrates, from various regions of Madagascar, have recently been acquired by the British Museum of Natural History. Amongst one of these, sent over by Mr. J. T. Last (collector for Mr. Grose-Smith), is a somewhat imperfect skull of strange appearance obtained with numerous fragmentary Chelonian, Crocodilian, Hippopotamus, and Æpyornis-remains from a marsh at Ambolisatra on the south-west coast of Madagascar. For this remarkable fossil Dr. Major proposes the name of *Megaladapis madagascariensis*, and the establishment of a distinct family of the sub-order *Lemuroidea*, of which *Megaladapis* appears to be a much-specialised gigantic member, being approximately three times the size of the cranium of the largest existing Lemurid.

The salient features of the skull are the enormous lateral development of the anterior inter-orbital portion of the frontals, extending over the small, thick-walled tubular orbits. The post-orbital frontal region is comparatively narrow and elongate, and separated by a slight contraction from the equally narrow parietal region, bearing a thick and flattened sagittal crest. The brain-case is low, short, and narrow, and placed at a considerably higher level than the elongate facial portion. Both the cranial and facial portion are somewhat bent upwards, the former posteriorly, the latter anteriorly. A striking general character is the remarkable *pachyostosis* (thickening) of the cranium.

The author points out that, in its peculiar features, this skull only carries to an extreme characters which are present, but in a much lesser degree, and in varying gradations, in the different members of the *Lemuroidea*, both recent *Lemuridæ*, and extinct *Adapidæ*. In the very simple pattern of the molars, the superior of which are of the pure tritubercular type, *Megaladapis* approaches closely to the Malagasy Lemurids *Lepidolemur* and still more to *Chirogaleus*.

The diminutive size of the brain-case (comparable only with what we find amongst the Marsupialia and the Insectivora) is viewed by the author, in this instance, as a degeneracy, other characters being equally indicative of a retrogressive evolution undergone by this Lemuroid.

It is strongly insisted upon, generally, that "low" organisation in Mammalia is by no means always synonymous with "primitive" organisation, and that retrogressive evolution is more frequently to be met with amongst Mammalia than is generally admitted.

As regards the geological age of *Megaladapis* and its associated fauna, one of whose members, the *Crocodilus robustus*, is still living in the lakes of the interior, evidence of various kinds goes far to prove that these sub-fossil remains represent a fauna which was living at a comparatively very recent period, and that man himself was also contemporary with it, and in part responsible for its destruction.

The author adduced evidence in support of the proposition that an older Tertiary vertebrate fauna will ere long be forthcoming in Madagascar.

"On Operators in Physical Mathematics. Part II." By Oliver Heaviside, F.R.S.

It is first shown how the ascending and descending series for the first cylinder function may be algebraically harmonised. If A is the ordinary ascending series in even powers, B the equivalent series in odd powers, and C the equivalent descending series which is most useful for numerical calculation, then $C = \frac{1}{2}(A+B)$. This contains the explanation of a former anomaly. A and C were known to the author to be equivalent as operators, also algebraically and numerically equivalent with positive argument. But when the argument is a pure imaginary A remains real, whilst C becomes complex. A becomes the original oscillating first cylinder function. C contains it and the second oscillating function as well. But the identity $C = \frac{1}{2}(A+B)$ explains it. Both sides remain identical when the argument is imaginary. The second oscillating function is brought in by B.

The generalised formula of which C is an extreme case is then investigated.

The extreme forms of the binomial theorem are then examined. It is shown that when the index is a negative integer the generalised formula becomes indeterminate, consisting of the two extreme forms combined in any ratio.

A more general operator and the equivalences to which it leads are then examined. There is sometimes satisfactory equivalence for numerical purposes by employing only the initial convergent portion of the divergent series, but this fails when the index of the operator is in the neighbourhood of a negative integer.

The general question of the meaning of equivalent and of divergent series is then discussed. The difference stated by Boole to exist between divergent series of the alternating and of the continuous type, in that the former may, whilst the latter cannot, be employed for calculation, appears to be groundless. They are alike in the respect alluded to. But the true meaning of numerical equivalence is unsettled, for there are many cases in which formulæ believed to be analytically and algebraically equivalent show no visible numerical equivalence.

Some generalised formulæ involving the logarithm are then discussed, and some independent verifications found. A formula for Euler's constant is obtained and examined.

One of these formulæ brings in the second cylinder function, which is discussed by means of an operator leading to it; also its connexion with the first solution, and of both with the corresponding two oscillating functions. Various analogies are pointed out, especially through an operator containing two differentiators, leading to elastic wave solutions. Some applications and extensions will follow in Part III.

"On a Failure of the Law in Photography that when the Products of the Intensity of the Light acting and of the Time of Exposure are Equal, Equal Amounts of Chemical Action will be produced." By Capt. W. de W. Abney, C.B., F.R.S.

The above law has been generally assumed. In some recen experiments, however, I have discovered that this law breaks down under certain conditions. Quite lately I have described the method of comparing the photographic value of sunlight with that of candle light (*Photographic Journal*, June, 1893), which was as follows:—A beam light would be admitted through a narrow slit to sensitive bromide paper stretched round a drum of about 4 inches in diameter. The drum could be caused to rotate round its axis at any speed up to about sixty revolutions per second, by means of an electromotor. Part of the experiment was to place an amyl acetate lamp in position at any convenient distance from the slit exposure being given for a fixed time during rotation. The slit was next replaced by a small square aperture, of some $\frac{1}{2}$ inch side, and other portions of the same paper were exposed to the amyl acetate light at the same distance, for varying but known exposures, with the drum at rest. On development the paper showed, amongst other things, a narrow band of deposit of the width of the slit caused by the light from the amyl acetate lamp, and a row of squares of varying blackness of deposit due to the different exposures given with the drum at rest.

By comparing the blackness of the band with the scale of blackness, the width of the slit would evidently be calculated, supposing the usually accepted law to hold good under all circumstances. On making such calculations in every case the calculated width of the slit was always considerably less than what it was in reality, the difference being far beyond that which would be caused by any error in the measurement. This led to an investigation into the cause of this difference.

The following experiment was made. The circumference of the drum with the paper stretched round it was 12·25 in. The width of the slit was arranged to be 0·012 in. The amyl acetate lamp was placed 2 feet from the slit, and a rotation of 30 per sec. was given to the drum for one exposure, and 1 per sec. for a second exposure. In the first case the time of exposure during each revolution was $\frac{0·012}{12·25} \times \frac{1}{30}$ sec., or about 1/30,000 sec.

The sum of the exposures during 20 min. was thus 1·176 sec. In the other case the exposure was

$$\frac{0·012}{12·25}, \text{ or about } 1/1000 \text{ sec.,}$$

and the sum of the exposures was, as before, 1·176 sec. Thus the first individual exposures had only $\frac{1}{30}$ of the duration of the second exposures, though in the aggregate they were the same.

A scale of blackness was made on the same paper, through a square aperture, without shifting the lamp, the exposures being $\frac{1}{8}$, $\frac{1}{4}$, $\frac{1}{2}$, 1, 2, 4, and 8 sec. The scale and blackness of the bands were measured accurately, and the times of exposure which had been given to each band, on the assumption that the law enunciated held good, was calculated and found to be for the first band 0·6 sec., and for the second band 0·91 sec., instead of 1·176 sec. which was really given in all. Another example is where the slit was opened to 0·11 in., and the time of exposure reduced from 20 to 10 min. It was found that in this case the exposures given on the same assumption were 3·7 sec. and 5·28 sec., the real exposure given being 5·36. Other experiments are quoted.

It is to be remarked that the more sensitive a surface is to radiation the less marked are the differences observable for the same speeds of rotation. This is what might be expected.

As an outcome of the experiments so far made, it seems that when exposures less than 1/1000 sec. are made, and the source of illumination is an amyl acetate lamp (Von Altneck's) placed 1 foot from the sensitive surface, the law fails.

The question of very low intensities of light acting, and of the sensitiveness to different spectrum colours, is now under consideration.

[*Note by the author*. It may be stated that it has subsequently been proved that the law equally fails where feeble intensities of light act on the sensitive surface.]

Geological Society, June 21.—Dr. H. Woodward, F.R.S., Vice-President, in the chair.—The following communications were read:—On composite dykes in Arran, by Prof. J. W.

Judd, F.R.S. The author proposed to apply the term "composite dyke" to any fissure which contains two or more distinct varieties of igneous rock, differing from one another in chemical composition or mineralogical constitution. Such dykes fall into two classes:—(1) Dykes in which differentiation has evidently taken place in the materials after their injection, as in the examples described by Dr. Lawson in Canada and by Prof. Vogt in Norway. (2) Dykes in which there is evidence of the reopening of the fissure after its first injection and the introduction of materials of totally different composition. It is this class of dykes of which such interesting illustrations are found in Arran. These Arran dykes belong to the latest volcanic eruptions of the British Islands; their analogues are found alike in the south of Scotland, and in the north of England and of Ireland. They are the infilled fissures along which sporadic volcanic outbursts took place after the extinction of the great volcanoes of the Inner Hebrides. The subaerial products of these later, and, for the most part, insignificant volcanic eruptions, have been all swept away by denudation, except at Beinn Hiant and the Sgúr of Eigg. The materials filling these dykes belong to two totally different classes—one distinctly basic, with about 55 per cent. of silica; and the other markedly acid in composition, with from 65 to 75 per cent. of silica. The basic rock is an augite-andesite, which passes sometimes into an intersertal and occasionally into an ophitic dolerite (tholeite and diabase); the glass of this rock shows a great tendency to separate from the phenocrysts. The acid rock is often a highly vitreous material ("pitchstone" or "pitchstone-porphyry") which by devitrification passes into various forms of felsite and quartz-felsite. These rocks, if we class them according to the nature of the porphyritic minerals they contain, fall into the several groups of vitrophyric and trachytoid lavas, to which the terms pantellerite, quartz-pantellerite, rhyolite, andesite, and dacite have been applied. The glassy groundmass in the whole of these rocks, however, is always abundant and its characters are remarkably uniform however much the phenocrysts may vary. The author pointed out that, while the peculiarities of the first class of composite dykes can be accounted for by selective crystallisation and liquation going on within the magma which has been injected into the dyke, no such explanation is sufficient in the case of the composite dykes of the second class. That the association of two totally different rocks in the same dyke is not accidental, the numerous and varied examples at Tormore sufficiently prove. Where, as in these cases, it is found that there is the greatest dissimilarity between both the crystals and the glassy groundmass of the two rocks, the differentiation has taken place in the magma, prior to its injection into the dykes, and before the work of crystallisation had commenced. Prof. Bonney, Mr. W. W. Watts, Mr. Hulke, and Mr. Teall took part in the discussion on the paper, and the author briefly replied.—Notes on an intrusive sheet of diabase and associated rocks at Robin Hood, near Bassenthwaite, by J. Postlethwaite. The positions of the outcrops of the igneous rock were described, and a grit-band was recorded as running parallel to the diabase. The diabase, and vein-stuff associated with it, have furnished antimony, lead, copper, and arsenic; and the same ores, with the exception of the last two, were also found in minute grains in the grit. Analyses of the grit and diabase have been made by Messrs. Hellon and Brockbank. Prof. Bonney has examined slides submitted by the author, and allowed his notes to be used in the paper. The igneous rock has produced slight metamorphism in the surrounding rocks of the Skiddaw Slates.—On two dinosaurian teeth from Aylesbury, by R. Lydekker. Two teeth from the neighbourhood of Aylesbury, believed to be of Portlandian age, were referred to the sames species as a tooth figured by De La Moussay from the Portlandian of Boulogne. The Aylesbury teeth were described, and the nature of the animal which possessed them was discussed.—On a new plesiosaur from the Waipara River, New Zealand, by Capt. F. W. Hutton, F.R.S. This specimen was shortly described by Sir James Hector in 1873. The author considered it more prudent to follow Mr. Lydekker in referring all the known New Zealand Cretaceous Sauropterygians to Leidy's genus *Cimoliosaurus*, and he therefore described this form as a new species of that genus.—Observations on the affinities of the genus *Astrocœnia*, by Robert F. Tomes. Researches recently made by the author relative to the structure of certain undoubted *Astrocœniæ* of the Gosau beds, having for their primary object the better understanding of the supposed species of the genus obtained from the Glamorganshire conglomerate, have been productive of results which will render a complete modification in the classificatory position of the genus imperative. The author gave a new definition of the genus, in which he did not include any species of an earlier date than the cretaceous period, all the so-called Jurassic *Astrocœniæ* being referable to other and quite distinct genera.—Description of a new genus of *Madreporaria* from the Sutton Stone of South Wales, by Robert F. Tomes. In the *Quarterly Journal* for 1885 is a detailed description of a coral from the Sutton Stone named *Astrocœnia gibbosa*. This specimen is not the type of the species, and a re-examination of it by the author has proved that it is not an *Astrocœnia*. Two other specimens have also been examined, and as a result of examination of the three the author is enabled to found a new genus *Styloseris*, of which a diagnosis was given, and the specific name *gibbosa* was retained for this, the only known species. The genus will take its place near *Clausastræa*, from which it differs by possessing a well-developed columella and increasing by both fissiparity and gemmation. Mr. Etheridge and Dr. G. J. Hinde took part in the discussion that followed.—Study of the dykes of Hope, Idaho, by Herbert R. Wood. A description was given of the geographical distribution and characters of acid and basic dykes traversing slates and quartzites along the northern shore of Lake Pend'Oreille, Idaho, accompanied by notes on the glaciation of the area. The microscopic features of the igneous rocks were also described.—The rise and fall of Lake Tanganyika, by Dr. Robert Sieger. The author referred to Mr. Carson's paper on the same subject in the Society's Journal for 1892. He himself believed the oscillation of level to be analogous to variations reported as occurring in other African lakes, and to be due to climatic change. He brought forward evidence in favour of the coincidence of change of level and climatic change, but did not believe that his views are by any means contradictory to those of Mr. Carson, for the phenomena may be explained by a combination of the influences of climate with those of mechanical agencies.—On Cheilostomatous Bryozoa from the Middle Lias, by Edwin A. Walford. The author described some forms of bryozoa from the *spinatus*-zone of the Middle Lias near Banbury, some of which had previously been classed with the Cyclostomata. The new material not only shows the opercular aperture but the opercula *in situ*, together with appendages and supra-oral ovicells characteristic of the Cheilostomata. In addition he also found giant cells (cistern-cells) of form quite dissimilar from the ordinary zoœcia and probably reproductive. He cited M. Jules Haime as having described in his magnificent monograph somewhat similar cells from the Inferior Oolite; and in the Oxfordshire Great Oolite bryozoa Mr. Walford found cistern-cells like the Lias species on some colonies like *Diastoporæ*. He contended that it is merely the acquisition of very well-preserved material which is needed to show the necessity of removal of many such species to the Cheilostomata. The name *Cisternophora* was suggested for the genus, of which several forms were described.

Royal Microscopical Society, June 21.—The Rev. Canon Carr in the chair.—Dr. J. E. Talmage, of Salt Lake City, Utah, exhibited and gave an account of some specimens of selenite found in the interior of a mound at South Wash, near Fremont River, Utah. As a rule, portions of selenite useful for optical purposes are measured by inches and weighed by ounces, but here he had found some which weighed 1000 lbs. The formation around the mound was mostly sand and clay, and the region bore everywhere strong evidences of weathering, by means of which the mound had been weathered out into relief. He had removed some twenty tons of the crystals, amongst which were many single crystals, measuring 4 to 5 feet in length, and entirely perfect, the most regular being 4 feet long with faces of 6 inches. One fine crystal, 5 feet long, had no less than nineteen small ones jutting out from it; twins and groups were also very common. Inclusions of sand, clay, and liquid were often present. He believed this to be a unique formation.—Mr. G. C. Karop read a letter on the subject of diseased beard-hairs.—Prof. T. Jeffrey Bell read a letter from Capt. Montgomery on the subject of chicken-lice, ticks from grass, and other parasites found in Natal.—Dr. Nias read a paper on the development of the Continental form of microscope.—A discussion ensued, in which Dr. Dallinger, Dr. Braidwood, Mr. Karop, Mr. Teasdale, and the author took part.—Mr. C. Rousselet gave a *résumé* of his paper on *Floscularia pelagica* and other new rotifers.

EDINBURGH.

Royal Society, June 19.—The Hon. Lord Maclaren, vice-president, in the chair.—Dr. H. R. Mill communicated a paper on the physical geography of the Clyde sea area. He considered specially the question of the distribution of temperature, discussing the observations made by the Scottish Marine Station staff on the West Coast of Scotland for March 1886 to October 1888, along with some other earlier and later observations made by Mr. J. Y. Buchanan and the Fishery Board for Scotland. In the North Channel, between Scotland and Ireland, the temperature was uniform from the surface to the bottom because of the action of the tides in mixing the water. The yearly average of the temperature of the Channel water was 2 degrees higher than that of the air of the Mull of Cantyre. The air temperature reached its maximum in the end of July, while the water temperature was greatest in the middle of September. The temperature varied greatly from surface to bottom on the broad shallow which stretches from Cantyre to Galloway, except at the time of the annual minimum, when it became uniform. The Channel water mixes there with the water from the great Arran basin. In that basin the temperature is the same from the surface to the bottom at the spring minimum in March, the lower layers being only slightly affected during the year—most so at the autumn maximum. The surface layers heat and cool rapidly; but the average temperature of the whole is always lower than that of the Channel, except for a month at the spring minimum. The maximum temperature in the basin occurs in October. In the more isolated sea lochs, such as Loch Fyne and Loch Goil, the absence of oceanic influence is more marked. Thus in Loch Fyne, though the temperature is nearly the same as at other places at the minimum period, it is colder during the rest of the year, and the difference between the surface and bottom temperatures is more marked.

July 3.—The Hon. Lord Maclaren, vice-president, in the chair.—Prof. J. Gibson read a paper on the chemical composition of sea-water.—Dr. Alex. Buchan described a diagram exhibiting the hourly variations of rainfall at Ben Nevis Observatory. The diurnal variations at Ben Nevis Observatory are much more marked than those at any other station on the globe from which Dr. Buchan had been able to get observations.—Prof. Tait gave a further discussion of the path of a rotating spherical projectile.—Dr. Noel Paton communicated a paper by Dr. Chasseaud on an experimental study of intra-ocular therapeutics.

DUBLIN.

Royal Dublin Society, June 21.—Prof. G. A. J. Cole in the chair.—The following papers were read:—Note on a graphitic schist from County Donegal, by Mr. R. J. Moss. The schist yielded on analysis a little over three per cent. of carbon.—On some Pycnogonida from the Irish coasts, by Mr. G. H. Carpenter. Eight species are enumerated, including two forms of *Phoxichilus;* and the various species are considered by the author to be so nearly related as to indicate that they are as yet but in process of differentiation.—A paper was communicated by Prof. A. C. Haddon on the post-embryonic development of fungia, by Captain Gilbert C. Bourne.

NEW SOUTH WALES.

Linnean Society, May 31.—Prof. David, President, in the chair.—The following papers were read:—Descriptions of new Australian Lepidoptera, with additional localities for known species, by T. P. Lucas.—Australian plants illustrated. No. v. *Angophora subvelutina*, F.v.M., by R. T. Baker.—The Silurian Trilobites of New South Wales. Part 2. The Genera *Proëtus* and *Cyphaspis*, by R. Etheridge, Jun., and John Mitchell.—Description of a new *Murex* from South Australia, by John Brazier.—Mr. Brazier exhibited a specimen of the South Australian *Murex polypleurus*, n.sp., described in his paper, a species which in the past, by the late Mr. G. F. Angas and other authors, has been confused with *M. pumilus*, A. Ad., from the China Sea, and Darros Island, Amirantes. Also a fossil specimen of *M. octogonus*, Q. and G., from New Zealand.—Rev. J. Milne Curran read a note recording the presence of a fossil Buprestid beetle in an earthy limonite at Inverell, N.S.W. The insect is represented by a portion of a metallic green elytron, and it is associated with Miocene fossil leaves and a species of *Unio*. He also showed a specimen of a Silurian fossil coral (*Heliolites*) from Molong, N.S.W., in a beautiful state of preservation.—Mr. Baker exhibited drawings and specimens in illustration of his paper.—Mr. Trebeck showed a specimen of a large freshwater prawn (*Palæmon ornatus*, Oliv.) from the Rewa River, Fiji.—Mr. C. T. Musson sent for exhibition specimens of a European slug, *Arion hortensis*, Müll., from New Zealand, where it is now not uncommon, though not yet recorded from Australia. Also, from the Kurrajong, N.S.W., specimens of the peculiar slug *Cystopelta petterdi*, Tate.

PARIS.

Academy of Sciences, July 10.—M. Lœwy in the chair.—Note on the history of the facts which have proved the existence of the coronal atmosphere of the sun, by M. J. Janssen.—Natural introduction of terms proportional to ether displacements (Briot's terms) in equations of motion of light waves, by M. J. Boussinesq.—On the relation which exists between the co-efficients of the formulæ of Coulomb (the magnetic formula), of Laplace and of Ampère, by M. E. H. Amagat.—On a differential equation of the second order, by M. Mittag-Leffler.—Proper vibrations of a medium indefinitely extended outside a solid body, by M. Marcel Brillouin. Investigating the infinitely small proper motions of an infinite gaseous atmosphere external to a sphere which is deformed in any manner and then rendered motionless, M. Brillouin arrives at an equation which defines the pitch and quality of the sound emitted by the sphere, and also plays an important part in the motion of solids in fluids. Thus the form and dimensions of the bullet define the pitch and the damping of the sounds produced; the form of the vessel defines the periods of the different waves which it produces whatever may be its (small) velocity, the longest waves playing an important part in the resistance experienced. Thus, also, the presence of a rigid obstacle in a solid elastic medium determines the periods proper to the external medium, characterising the form and the properties of the body. There is every reason to believe that the waves emitted by metallic vapours correspond for the greater part to vibrations peculiar to the external ether, as will be shown in a detailed study of optical theories about to appear in the *Annales de Chimie et de Physique.*—On the realisation of constant temperatures, by M. Gouy. A criticism of M. Berget's work to determine the constant of gravitation, on the ground of the enormous difference produced in the gravimeter by a small difference of temperature.—On the electric transference of heat in electrolytes, by M. Henri Bagard. Two cylindrical glass tubes are fixed vertically in the corks of two vessels into which a current is conveyed so as to pass into the first vessel, up through the first tube into a reservoir containing a solution of some salt like zinc sulphate, down through the other tube and out by the other vessel. The lower portion of the tubes is kept at a lower, the upper at a higher temperature. A distinct Thomson effect was observed on sending a current from twelve small Daniell's through the arrangement, heat being conveyed in the direction of the current, as was easily shown by the variation of resistance, which in liquids decreases rapidly at higher temperatures.—On pyrosulphochromic hydrate, by M. A. Recoura.—On the combinations of selenious acid with molybdates, and on molybdoselenious acid, by M. E. Péchard.—On the iodosulphides of arsenic and antimony, by M. L. Ouvrard.—On the dissociation of calcium plumbate, by M. H. le Chatelier. In Kassner's process for the manufacture of oxygen, the following reaction is utilised:

$$PbO_2.2CaO = PbO + 2CaO + O.$$

Experiments were made with a view of determining the advantages or otherwise of this process as compared with barium peroxide. It was found that the disadvantage of the new method lay in the fact that it required a temperature of 900° instead of 700° for the oxygen to be dissociated at a pressure of 0·1 atmosphere. On the other hand, the plumbate, being easily fusible, absorbs oxygen more rapidly and completely, and the air need not be previously desiccated and decarbonated.—On benzoylcinchonine, by M. É. Léger. Action of sulphuric acid upon pyrocatechine and upon homopyrocatechine, by M. H. Cousin.—On a process of directly combining ethylenic and aromatic carbon compounds, by M. A. Brochet.—Attempt at the diagnosis of isomeric amido-benzoic acids and some other aromatic compounds, by M. Œchsner de Coninck.—On geraniol, by M. Ph. Barbier.—Influence of the acidity of musts upon the composition of the phlegms, by M. L. Lindet.—Greater assimilability of the nitrogen from recently formed nitrates, by M. P. Pichard.—On the composition of lime-tree "honey," by M. Maquenne.—On a new terrestrial Gregarina of the melolonthid larvæ of Provence, by M. BERLIN.

Physiological Society, May 19.—Prof. du Bois Reymond, President, in the chair.—Dr. Benda, in continuation of his remarks at the last meeting, spoke on certain questions connected with cell-division, dealing first with the value of double-staining. He then made a communication on the extra nuclear origin of the nuclear spindle and its relation to the centrosoma, and lastly on the median cell discovered by Flemming, which appears after the equatorial transverse division has become formed in the dividing cell.—Prof. Gad gave an account of experiments made by Dr. Rosenburg on the transplanting of slips of small intestine into the bladder. The experiment was successful; the functions of the bladder remained normal, and investigation showed that the muscular coat of the intestine had grown into that of the bladder, while the mucous membrane had grown up through the flattened epithelium of the organ.

June 9.—Prof. du Bois Reymond, President, in the chair.—Dr. Loewy had gone carefully into the methods of blood-titration, and concluded that the most convenient and certain way of determining the alkalinity of blood is to dilute it with a solution of magnesium sulphate and to add acid until a drop of the mixture just reddens litmus. In connection with this Prof. Zuntz gave an account of some experiments of his own and of Prof. Lehmann on the nature and compounds of the acids and bases of blood. He drew special attention to the results of passing carbon dioxide through blood whereby the alkalis leave the corpuscles and pass into the plasma as the result of a splitting up of their compounds with proteids and their conversion into diffusible carbonates.—W. Townsend Porter communicated the results of his experiments on the coordinating centres of the cardiac ventricle. Starting from the fact that the function of the centres is suppressed when the blood-supply is cut off, he had ligatured the coronary artery, supplying the septum, in a number of animals. In all cases the animals lived for many hours and even days after the operation, from which fact he considered he had disproved the existence of any coordinating centre in the septum.

Physical Society, June 2.—Prof. von Helmholtz, President, in the chair.—Dr. Rubens gave an account of experiments he had made, together with Dr. du Bois, on the permeability of metallic wire gratings to polarised heat rays. As is well known, Hertz's experiments on electric oscillations brought them into close relationship to the properties of light-vibrations, as shown by reflection, refraction, and polarisation. The fact that metallic gratings act as polarisers towards electric waves, inasmuch as the waves can only pass through when the wires of the grating are parallel to them, has no analogue in the case of light, since linearly polarised light can pass through a grating whatever be its position. On the assumption that this difference is dependent simply on the fact that light waves are too small for the gratings employed, the authors had experimented with the longer heat-rays and gratings of extremely narrow aperture. The latter were made of the finest wire (gold, silver, copper, and iron), the intervals between the wires being ·0025 mm., and the rays of a zirconium flame, up to W.L. 6μ were examined. The ocular of the spectroscope carried a very sensitive bolometer. It was found that with each of the gratings the ultra-red rays behaved like electric waves; those rays which vibrated at right angles to the plane of polarisation passed through a grating placed parallel to their plane, in threefold extent, as compared to the amount which passed when the grating was at right angles. This result was obtained with different metals with varying wave-lengths of the rays, *e.g.* with silver by W.L. above 2μ.—Dr. Krigar-Menzel reported on the present state of the experiments he is making together with Dr. Richarz on the diminution of weight at increasing altitudes. A balance is provided at each arm with two pans, one above the other at a distance apart of 2·2 m. With this balance two weights are determined, of which one lies in the upper pan, the other in the lower. The weighings are then repeated on both sides, and thus the difference of the weights when in the upper and lower pans is ascertained. In the next place a massive leaden block is built up between the two pans and the weighings are repeated. Up to the present time the weighings without the lead mass are alone complete. The block is, however, in position, and a few preliminary weighings have been made, from which it so far appears as if the presence of the lead had done away with the difference of the weights when in the upper and lower pans.

[NOTE.—In the report of the Physical Society, NATURE, vol. xlviii. p. 144, column 2, five lines from the top—"the vapours of these metals similarly gave an emission-spectrum following on the absorption spectrum"—for "similarly" read "neither," and for "following on" read "nor."]

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Heat: M. R. Wright (Longmans).—Aids in Practical Geology, 2nd edition; Prof. G. and J. Cole (Griffin).—An Introduction to the Study of the Diatomaceæ: F. W. Mills (Iliffe).—Diagnostik der Bakterien des Wassers: Dr. A. Lustig (Jena, Fischer).—Euclid's Elements of Geometry, Books v. and vi.: H. M. Taylor (Cambridge University Press).—Acoustics, Sound (Advanced), enlarged edition: W. Lees (Collins).—A Study of the Languages of Torres Straits, Part 1: S. H. Ray and A. C. Haddon (Dublin).—The Arctic Problem: A. Heilprin (Philadelphia, Contemporary Publishing Company)—Exploration of Mount Kina Balu, North Borneo: J. Whitehead (Gurney and Jackson).

PAMPHLETS.—Ueber die Typen der Küstenformen: Dr. A. Philippson.—Sir F. Ronalds, F.R.S., and his Work in Connection with Electric Telegraphy in 1816 (Simpkin).

SERIALS.—Medical Magazine, July (Southwood)—The Lingualumina, Parts 1 and 2: F. W. Dyer (London)—Proceedings of the Society for Psychological Research, June (K. Paul)—The Book of the Fair, Part 1: H. H. Bancroft (Chicago, Bancroft).—Botanische Jahrbücher für Systematik Pflanzengeschichte und Pflanzengeographie, Sechzehnter Band, iv. u. v. Heft (Williams and Norgate).—Annals of Scottish Natural History, July (Edinburgh, Douglas).—Notes from the Leyden Museum, July (Leyden, Brill.)

THURSDAY, JULY 27, 1893.

THE ROTHAMSTED JUBILEE.

ON Saturday next a large gathering of scientific men will assemble in the village of Harpenden to do honour to two investigators who have just completed fifty years of joint labour.

The occasion is unique. It can have happened but seldom that two men have continued their joint scientific investigations for a period like the present; but there are other circumstances, apart from this, which mark the event about to be celebrated as one of exceptional interest. The Rothamsted agricultural experiments are indeed a piece of work of which England may well be proud. They form a splendid example of what is sometimes accomplished amongst us by purely individual effort. The extensive series of costly experiments, carried out on a large scale both in the field and in the laboratory, and with results of national importance, has been maintained for more than fifty years at the sole expense of one man. Nor is this all. Sir J. B. Lawes has made provision for the continuance of these investigations. The laboratory and the experimental fields, with £100,000, have been placed in the hands of trustees, and the future management of the investigations has been entrusted to a committee, the members of which are elected by various scientific societies.

But it is not only as a striking example of individual zeal and munificence that the Rothamsted agricultural station is remarkable, it is equally so if we regard the character of the work performed. Many of the most important problems connected with agriculture can only be satisfactorily studied by actual experiments in the field; such experiments require to be carried out on a large scale and continued for many years. Boussingault was, we believe, the first who sought to ascertain the chemical statistics of agriculture by a quantitative examination of the actual crops of the farm, and by a study of the constituents of soil, of manure, and of rain-water—the various factors which determine the amount of the harvest. But if the work of Boussingault stands first in order of time, the work of Lawes and Gilbert at Rothamsted immediately follows it, and has been continued for such a much longer series of years, and developed in so many new branches of inquiry, that it is to Rothamsted that the agriculturist has long looked for information concerning the fundamental facts of agricultural chemistry.

The field experiments at Rothamsted are peculiar to the place; in very few of the now numerous agricultural stations in foreign countries has systematic work of this kind been attempted; in none has the work been so extensive and so long continued. No less peculiar to Rothamsted has been the laborious investigation into the composition of oxen, sheep, and pigs in various stages of fattening, and into the chemistry of the fattening process. Of the laboratory investigations we may mention the more recent inquiry into the causes and conditions of the production of nitrates in soil, and respecting the quantity of nitric nitrogen in soils of various history, and in drainage and well waters. But we must not here attempt an enumeration of published Rothamsted work, which, according to the last report, has furnished the matter for 125 papers.

Rothamsted is by much the oldest of existing agricultural stations. The earliest German experimental station was founded in 1852, the earliest in the United States in 1875. The first agricultural experiments of Mr. Lawes seems to have been made in 1837; in this and the two following years he tried numerous experiments on farm crops grown in pots. His trials in the field commenced in 1840. In 1843 he was fortunate in securing the services of Dr. J. H. Gilbert, a former pupil of Liebig's, who henceforth took the superintendence of the chemical part of the investigations. Dr. Gilbert has devoted his life to the conduct of the Rothamsted experiments, and the valuable results which have been obtained are largely due to his untiring energy, and to the method and order which his character has impressed upon the work. The jubilee to be celebrated this week is reckoned from the year when Dr. Gilbert began to take a share in the work; the same year also saw the first of the experimental wheat crops sown in Broadbalk Field, which, at the present time, bears its fiftieth successive crop, having grown wheat without intermission during half a century. Numerous honours have been conferred on Messrs. Lawes and Gilbert in the course of their long career. Our Universities have bestowed on them degrees. The Royal Society in 1867 awarded them a royal medal. The Society of Arts has during the current year decided to present them with its Albert Medal. Foreign societies and academies have elected them members of their body. In 1882 Mr. Lawes received a baronetcy from the Queen.

The jubilee commemoration of the present week took its rise at a meeting held in the rooms of the Royal Agricultural Society on March 1, the Prince of Wales occupying the chair. A committee of distinguished men, with the Duke of Westminster as chairman, and Mr. Ernest Clarke, Secretary to the Royal Agricultural Society, as secretary, was appointed to carry out the scheme. The celebration on Saturday will consist, as the readers of NATURE are already aware, in the unveiling of a granite memorial erected in front of the laboratory; in the presentation of congratulatory addresses to Sir J. B. Lawes and Dr. Gilbert; and in the presentation to Sir J. B. Lawes of his portrait, by Hubert Herkomer, R.A. It is hoped that the Right Hon. Herbert Gardner, M.P., the Minister for Agriculture, will preside.

The laboratory, in front of which the celebration is to take place, is itself a testimony to the appreciation with which the labours of Lawes and Gilbert have been regarded. It is not the laboratory originally employed in the early years of the experiments; this was a barn which had been fitted up for chemical work, and has long ago been pulled down. The present laboratory was built and presented to Sir J. B. Lawes in 1855 by a number of agriculturists, at a time when agriculture was a more profitable pursuit than it is at present. Since then the needs of the work have grown, and a large storehouse for soil and crop samples has been erected by the side of the new laboratory.

Of greater interest to most visitors than the laboratory is the old manor of Rothamsted. This charming red brick building dates from 1470, though, like most old buildings, it has since undergone alteration and enlargement. This manor house has been the home of Sir J. B. Lawes' ancestors since 1623. The history of the family is remarkable. It was in 1564 that Jacques Wittewronge came to England from Flanders in consequence of the religious persecution then prevailing. The family first resided in Buckinghamshire; they afterwards purchased the manor of Rothamsted. Sir J. B. Lawes is a descendant of this family through the female line.

In the manor house of Rothamsted Sir J. B. Lawes was born in 1814. His whole life has been one of great activity; probably few men have accomplished more work. Though for many years a hard-working man of business, he has always loved a retired country life, and has been rarely seen at public meetings. A keen observer and an untiring experimenter, he has given his whole mind to the problems of agriculture, while his great practical sagacity has enabled him to grasp at once the real bearing and importance of each new fact. Probably no one has taken a more practical and wide-reaching view of agricultural questions than Sir J. B. Lawes. When the present century is concluded, the work of Lawes and Gilbert at Rothamsted will be reckoned among the prominent achievements deserving a grateful record.

THE ORIGIN AND DEVELOPMENT OF MUSIC.

Primitive Music: an Enquiry into the Origin and Development of Music, Songs, Instruments, Dances, and Pantomimes of Savage Races. By Richard Wallaschek. (London: Longmans, Green, and Co., 1893.)

MR. WALLASCHEK has not only compiled with laborious care what appears to be an exhaustive account of the music of so-called savage races, but has based upon the foundations thus laid an able and interesting discussion on the origin and development of music. It is with the latter rather than the former part of his work that I propose to deal in this notice.

The author is led by his researches to regard rhythm as the primitive and primary constituent of music, while melody was in the primitive state, and has remained, secondary and accessory. Harmony is not to be looked upon as a comparatively recent invention among European races. "As soon as music passes the mere rhythmical stage the lowest races in the scale of man begin to sing in different parts in intervals as well as with a bass accompaniment." The order of development therefore is, first rhythm, and then, possibly coeval one with the other, melody and harmony. With what then is the rhythm of primitive music associated? With the rhythm of the dance. If I understand the author rightly this association is, in his opinion, an invariable one in the origin of music. Now, "in dance-music the idea is to excite the performer and to fatigue him even to exhaustion. The musical dance-chorus is of a social character; music keeps the company together and enables them to act simultaneously." I quote here from the author's summary, which is no doubt somewhat condensed and elliptical. One can hardly suppose that "fatigue even to exhaustion" was part of the primary "idea" (understanding by this word aim and object) of the dance. Would it not have been better to say that a part of the "idea" was to test and tax the powers of endurance of the performers? Be this as it may, war, the chase, and sexual passion afford the underlying motives of that emotional excitement which finds its expression in the rhythm of the dance; and thus this rhythm becomes most intimately bound up with practical life-preserving and life-continuing activities, or, in other words, with activities which are distinctly of natural-selection value. The large share taken by women in the dance and primitive music enables them to contribute not ineffectually towards the success of the tribe in its struggle with other tribes.

"If it be asked whence the sense of rhythm arises, I answer," says the author, "from the general appetite for exercise. That this occurs in rhythmical form is due to sociological as well as psychological conditions. On the one hand there is the social character of primitive music, compelling a number of performers to act in concert. On the other, our perception of time relations involves a process of intellection," and hence an appreciation of time, order, and rhythm. I would suggest that the psychological basis of the "sense of rhythm" might be found in experiences more primitive than any process of intellection—in the organic rhythms of our daily life. We cannot walk nor breathe except to rhythm; and if we watch a little child we shall obtain abundant evidence of rhythmic movements. This I should have placed first; and then the concerted rhythms of social activities. "Whence," asks Mr. Wallaschek, "does the general desire for exercise arise? Mr. Herbert Spencer's theory affords," he replies, "the most valid explanation. It is the surplus vigour in more highly evolved organisms, exceeding what is required for immediate needs, in which play of all kinds takes its rise; manifesting itself by way of imitation or repetition of all those efforts and exertions which were essential to the maintenance of life (*e.g.* the war-dance)." In explanation of the term "surplus vigour" the author does well to point out that this is not meant to imply a surplus beyond the needs of the organism at any time of its life, but a temporary surplus beyond its needs in times of unmolested peace and plenty.

While accepting Mr. Spencer's general theory of surplus vigour, Mr. Wallaschek is not prepared to accept the speech-theory of the origin of music. "Whereas Mr. Spencer," he says, "seems to think that musical modulation originates in the modulations of speech, I maintain that it arises directly from the rhythmical impulse." Without presuming to decide between Mr. Herbert Spencer and Mr. Wallaschek, I venture to point out how much depends upon the exact definition of "music" and of "speech." Mr. Wallaschek, as we have seen, regards primitive music as essentially rhythm without necessary association with either melody or harmony. It is a mere tone-rhythm in association with dance-rhythm. Whether to such tone-rhythm the term "music" can be satisfactorily applied, I am myself inclined to question. But that is another matter. We are bound to accept for the purposes of his argument the definition which an author sets forth. All that Mr. Spencer has written on the subject, however, leads us to suppose that for him music includes melody, or at least cadence. And I take it that in his speech-theory it was the melody or cadence of music that he specially had in view. Now "speech" may either mean intentional suggestion by means of vocal sounds, or such suggestion by means of vocal sounds rendered articulate and ordered in propositions. Taking the former and broader meaning, it appears to me that the vocal sounds associated with the dance must be regarded as having suggestive value to those who are acting in concert, and as possessed of rhythmic import; and that, further, from these vocal sounds arose the melodic and harmonic elements of music. Personally, I should advocate the more restricted use of the word "speech," and should prefer to say that both music (including melody) and articulate speech are of vocal origin. And this, I take it, comes very near, not only to Mr. Wallaschek's own view, but also to that of Mr. Spencer against whom he is arguing. The association of these vocal sounds with the concerted activity of the dance is quite in line with the suggestion of Noiré, adopted by Prof. Max Müller, that the origin of speech is to be sought in the vocal sounds uttered during the performance of common social actions.

There are many other points in Mr. Wallaschek's book to which I should be glad to draw attention did space permit. His discussion of the origin of the diatonic scale is of interest and value. He is on firm ground in his contention that primitive music is associated with life-preserving and life-continuing activities, and was thus in its early phases fostered and developed by natural selection. This few evolutionists would care to question. But concerning the development of music, *as an æsthetic activity*, he does not suggest anything very definite. He holds that there is nothing in the history of musical development to justify a belief that the inheritance of acquired faculty has been a factor in the process; and here I think he is right so far as definite evidence goes. He also holds that the great musician is a man of power who has devoted his faculties to music, and who would have been great as a painter or as a poet had circumstances led him to devote his faculties to these arts. And here again I believe that he is right. But the question is, What has guided musical development along the special lines that it has taken in Europe? I do not think that Mr. Wallaschek will contend that the guidance has here been that of natural selection. But guidance there has been. No doubt in this as in other matters of art, man has been giving objective expression to his ideals. But what has led the ideals to take the form they have taken? This is one of the most difficult problems presented by the psychology of æsthetics; and it no doubt lies somewhat beyond the field of primitive music on which Mr. Wallaschek has given us a work of real merit and value.

C. LLOYD MORGAN.

EARLIER RECOLLECTIONS OF MARIANNE NORTH.

Some Further Recollections of a Happy Life, selected from the Journals of Marianne North, chiefly between the Years 1859 *and* 1869. Edited by her sister, Mrs. John Addington Symonds. Post 8vo, pp. 316, with two portraits and a sketch. (London and New York: Macmillan and Co., 1893.)

THIS volume might very appropriately have borne the title of "Earlier Recollections," inasmuch as it describes the life of Marianne North antecedent to the period comprised in the two volumes previously before the public. On this point Mrs. Symonds says in her preface: "When publishing the former volumes of my sister's autobiography, it was thought wiser to cut out some of the earlier chapters describing well-known ground, in order to make room for those more distant journeys by which her name had become known to the to the world. But the unexpected success which that book met with induces me now to add those first European journeys, with one through Egypt and Syria."

It is probable that these sketches of travel in Europe, Egypt, and the Holy Land, from twenty-four to thirty-four years ago, will appeal to an even wider range of readers than the accounts of Miss North's later journeys to the furthermost parts of the earth, after she had become so widely known as a traveller and a painter. The same freedom in style and criticism pervades this as well as the former volumes. Briefly, it may be described as a rapid and graphic narrative of the incidents of travel, interspersed with lively observations on peoples and places, on plants and animals, and on the physical features of the countries traversed, with here and there historical allusions and reflections. The earlier journeys, that is from 1859 to 1869, were made in the company of her father; and her sister, who has edited these recollections of long ago, was also of the party up to 1867, and therefore well qualified for the task. The first trip was to the Pyrenees and Spain, by way of Jersey, St. Malo, Rennes, Tours, Bordeaux, and Pau. A stay of a month was made at Luchon, where Miss North made her first attempt at landscape painting. Thence they went to Barcelona, Tarragona, Valencia, Madrid, Toledo, Granada, Malaga, Seville, and Cadiz, and home by sea. This trip occupied nearly six months, and is described in less than thirty pages! In fact, the pace is tremendous, though the travelling in Spain was nearly all by diligence, which was very exciting if not absolutely dangerous. However, only the main incidents are touched upon, and the reader finds himself in a fresh place on every page. In 1865 and 1866 Egypt and Palestine were visited. Even at that period Miss North painted very assiduously, but a painting of doum and date palms, on the Nile above Philæ, is the only one in the North Gallery at Kew of that date. After the death of her father, in 1869, Miss North continued to travel, in order to forget her loss; first visiting Mentone and then Sicily. Much of her time was occupied in painting, though only one picture, the Papyrus growing in the Ciane, near Syracuse, is in the collection at Kew. All the rest, with one other exception alluded to above, are the work of her more distant journeys of later date. But all persons who have read the entertaining and interesting descriptions of the longer journeys will be anxious to possess the present volume, and will, we predict, not be disappointed with the contents. Should it, however, run to a second edition, the words and phrases from various foreign languages scattered through the book might be expunged or corrected. It is rather odd to find a priest or monk designated as "Signor Cannonico"; and an extra syllable in Beleuchtung does not improve it. There is, too, an unfortunate slip in the preface and on page 133, Elephantine Island being referred to as the Island of Elephanta. W. B. H.

OUR BOOK SHELF.

Elements of Psychology. By James Mark Baldwin, Professor Elect in Princeton College. (London: Macmillan and Co., 1893.)

UNDER the above title Prof. Baldwin has written a shorter text-book which, as he states in the preface, differs from his larger work, the *Handbook of Psychology* (reviewed in these pages vol. xliii. p. 100, and vol. xlvi. p. 2) mainly in its omissions. Like its larger predecessor, this book deals largely with "apperception" regarding, erroneously as we think, the selective synthesis observable in mental products as something wholly different from anything which is to be found in other departments of natural knowledge. "In the physical world," he says, "we find no such unifying force as that known in psychology as the activity of apperception." Although there is much in this work, as in its predecessor, with which we are in hearty but friendly disagreement, it appears to us to possess the great merit of giving abundant evidence of independent thought and treatment. It will, in the hands of senior students, stimulate them to thought and criticism—such criticism as the teacher who is in earnest welcomes like a breath of keen fresh air. The chief fault of the book is that its pages are somewhat unduly crowded with details. C. LL. M.

An Introduction to the Study of Geology. By Edward Aveling, D.Sc. (London: Swan Sonnenschein and Co. 1893.)

DR. AVELING has compiled a volume better, in many respects, than any of its kind. His arrangement of matter has much to commend it, and his descriptions are of the concise character regarded with favour by those who incline to a pabulum consisting of concentrated essence of knowledge. The book is another of that large class "specially adapted for the use of candidates for the London B.Sc. and the Science and Art Department Examinations." Intending examinees would do well to obtain it, but the student who loves geology for its own sake will hardly find the contents to his liking.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Publication of Physical Papers.

As most people seem afraid to enter on this discussion, it is appropriate for others to rush in. I have not, however, anything very much to say, except (1) that it seems to be a subject which in its intersectional aspects is suited to oral discussion at a meeting of the British Association, and (2) that if the *Beiblätter* were regularly and intelligently translated a good deal of the necessary physical abstracting would *ipso facto* be done.

Abstracting on a large scale is difficult work, and the English genius scarcely runs in that direction. It seems to me a pity for a greater number of competent persons to be engaged on it than is really necessary, and if the Germans are good enough to do it for the world, why should we not recognise their work and utilise it to the utmost?

It will be answered, so we do; everyone sees the *Beiblätter*. Yes, and I suppose about half a dozen effectively glance through it. Not everyone is capable of taking in a page of German at a glance, as one can English, and, for myself, I find that what I have half-read in a foreign tongue has a fatal facility for slipping from the memory.

I need not labour the point, it is simply this—that whereas a weighty paper of known and conspicuous importance in one's own object can, if necessary, be worked at and utilised in almost any ordinary language, papers of uncertain value or of only approximate interest must be skipped altogether unless they can be skimmed; and that the skimming process in a foreign language is impossible to all but a few favoured physicists, whatever may be the case with chemists.

If an English edition of the *Beiblätter* were regularly published, the only abstracts that would remain to be done by us would be the contents of Wiedemann's *Annalen* and possibly of a few American or provincial publications.

But there are other questions besides that of abstracts; and chief among them is the question of central publication of all the English papers of importance which at present are difficult to procure.

These occur mainly in connexion with the Societies of Dublin, Cambridge, and Edinburgh. Few other Societies in the British Islands claim or possess a monopoly over papers presented to them. Nearly all except these three are, I suppose, now used chiefly for contemporaneous or *ad interim* publication, and any serious results are communicated by the author to some central organ. If that is not so it ought to be so. If an author has a good result which he will not publish, he can hardly be compelled. It ought, however, to be clear that mere printing in a half-known local journal is not proper publication at all; it is "printing for private circulation." Biologists are, I am told, given to err in this direction, each small society pluming itself on publishing memoirs in order to receive "exchanges," a ghastly and polyglot form of literature which may be catalogued but can hardly be read. However, biologists are doubtless the best judges of their own procedure, and what is suited to a copious and readily illustrated subject is not likely to be well adapted to physics.

Coming to the really central organs (whether general or special), the Transactions and Proceedings of the Royal Society, the *Philosophical Magazine*, and NATURE; most British and Colonial physicists can see them without trouble, and the *Phil. Mag.* is seen all over the world. Merely a few slight changes are needed in connexion with these organs. The Proceedings are largely a journal of the doings of the Royal Society, and as such are not specially edifying to outsiders. In consequence of this, perhaps, and also in consequence of the multifarious nature of the subjects treated simultaneously, the papers included therein do not get widely known. The Transactions are all published as separate memoirs, so that there need be no difficulty for an isolated worker not a Fellow to procure a copy, if the contents are freely advertised. But I would suggest that the cost of these separate copies and of each number of the Proceedings, is much too great. As one not at all behind the scenes, I am ignorant of the reasons for this high price, but I should think it might be a proper expenditure of some of the Society's wealth if their publications could by a considerable reduction in price, even to a nominal figure, be made much more widely available.

For most societies the method of publication invented, or at any rate adopted, by the Physical Society of London, seems to me well worthy of imitation. Until this is done, there remains the question of making the valuable papers which occasionally, or perhaps frequently, appear in NATURE or other weeklies, in the Transactions of the Cambridge, Dublin, and Edinburgh Societies,[1] and sometimes in the Proceedings of the Manchester and other provincial societies, more accessible to foreigners and incidentally to ourselves. This could be done by central reprinting, either in a new special publication, or in some extra

[1] I do not specifically mention the semi-technical societies, such as the Institution of Electrical Engineers, though often it is difficult to draw the line, and some of their papers, too, might be included.

volume of an already existing publication. I feel that it ought to be in some neutral, or non-society journal, to avoid arousing jealousy. If either the Royal or the Physical Society could take the matter up and arrange for, say, an extra half-yearly number or an extra annual volume of the *Phil. Mag.*, the thing could be done.

If they could also at the same time arrange for a prompt translation and republication of important foreign papers, many of us would be grateful; cash has hitherto been the main difficulty, but perhaps with the abundant funds at present available across the Atlantic, we may hope for something large and cosmopolitan in this direction before long from our co-linguists there. I commend this to the notice of the energetic secretary of the Smithsonian Institution. Everything tending to mitigate the miserable evils of the confusion of tongues would be eminently welcome, and whenever the whole earth has again the happiness of being "of one language and of one speech," I trust that that speech will be English.

OLIVER J. LODGE.

THE publication of a digest of the scientific papers which have appeared in the English language during even a limited period would entail serious difficulties. In the first place, the expense of printing would be considerable, and it would also be hardly possible to obtain the services of men competent to perform the task without paying them an adequate fee. In the second place, a satisfactory digest could not be published without the co-operation of the various scientific societies; and everybody who has had any experience as a member of the governing body of any club, society, or other institution is well aware of the difficulty of getting a dozen men, many of whom represent conflicting interests, to agree upon any definite scheme.

Still, I believe that the foundations of a scheme, which would be capable of development, might be constructed on somewhat the following lines:—

In 1889 the London Mathematical Society printed an index of all the papers published in the first twenty volumes of their Proceedings. The authors were arranged in alphabetical order, and their communications according to the dates of publication. This index will no doubt be brought up to date and reprinted, and I shall suggest (if I am then a member of the council) that an index of *subjects* shall also be printed, consisting of two parts viz. pure and applied mathematics, arranged in alphabetical order as regards *subjects*. Now if every scientific society which deals with pure and applied mathematics, or with experimental subjects which are capable of mathematical treatment, would co-operate with the London Mathematical Society in publishing an index of their own papers, arranged, printed, and paged in the same manner, it would be quite easy, by a rearrangement of the type, to print a joint index of all papers on these subjects which have been published, during the last twenty or thirty years, by the societies which co-operate. Each society would bear the expense of printing the original index of its own proceedings; and a proportionate part of the expense of printing and publishing the joint index, together with the profits derived from its sale, would be borne by and received by each society. It will be observed that the above scheme only contemplates a double index arranged according to authors and subjects, and not a *digest*; but every one who has had a little experience in hunting up papers, and also, I may add, law cases, will appreciate the value of such an index.

The editors of the Law Reports always insert under the title of each case a short paragraph in small print, giving an account of the points of law with which the case deals, from which the triennial digest is compiled; and if scientific societies would in future require authors to adopt the same course, the paragraph could be put into the index, and would be invaluable. The head-note need not amount to more than a few lines, and should describe the object of the investigation without entering into more detail than is absolutely necessary.

The various reports of the British Association on the progress of different branches of science contain much valuable information, and some of them might with advantage be printed in the index in a condensed form.

In conclusion, I would suggest that the governing bodies of the different societies should discuss this matter, and that a committee of delegates from those societies, which approve of united action, should be formed. The delegates ought, however, to be practical men well-versed in business, and able and willing to devote their time to the consideration of this question.

A. B. BASSET.

Birds' Methods of Steering.

THE flight of birds still presents several unsolved problems. How they steer, has never been fully explained. With the naked eye or, still better, with a field glass, many of them can be seen to use their tails, lowering the left or right side according to the direction in which they wish to go. This use of the tail as a rudder is much practised by pigeons, jackdaws, rooks, larks, swallows, housemartins, sandmartins, and I believe, by most of our common birds. Gulls let down a foot on one side or the other, and, no doubt, many other web-footed birds do the same. Still a rook or pigeon that has lost his tail manages to steer well, the chief result of the loss being that he cannot stop suddenly, nor float upon the air, but must take rapid strokes with his wings. What other method, then, has the bird of steering? One fact that bears upon this question can be easily observed. When a bird wishes to turn to the left he moves the centre of gravity of his body and flings himself on his left side, the right wing pointing upward and the left downward. How does he throw himself into this position? Most writers say that it is by striking harder with one wing than the other. In turning to the left the right wing would give a vigorous stroke, and so raise the right side of the body more than the left. At first sight it seems as if this explanation could not be the true one, since after a hard stroke the right wing should be lower than the left, which has only given a gentle one, and yet it is the right wing that is raised. But we must not be too hasty in drawing conclusions from this. When the down stroke takes place the wings do not descend far; the body rises so that the end of the wing appears to have described a much greater arc than it has done in reality. If, then, with the right wing a much harder stroke is given than with the left, the right side of the body will at once be raised, and the whole bird will be thrown upon its left side, while the movement of the wing itself may not be enough to be perceptible. If birds are watched as they fly, one wing seems always to be at the same angle to the body as the other, so that a straight line connecting the tips of the wings would pass through the two shoulder joints, or be parallel to a line passing through them. Instantaneous photographs of birds on the wing seem to me to bear this out. One wing may point up and the other down, but that is through the swaying of the whole body to one side or the other. In spite of this there may be an inequality of stroke that escapes detection, and without assuming this it seems on first thoughts difficult to account for the extraordinarily rapid turns made, for instance, by the swallow. But supposing that what appears to be the case is really so, viz., that equal force is put into both wings, there remains another possible explanation of this movement of the centre of gravity to the left or right in turning. If a bird wishes to steer leftwards, he may bend at the waist towards the left. So much has been said about the rigidity of the bird's backbone that its suppleness at a point just anterior to the ilium has been overlooked. I find that a swallow's vertebral column will bend at this point so as to form an angle of 150°; in the case of a kestrel it is 156°, of a tern 155°, of a sandmartin much the same as in the case of the swallow, in the case of a duck 165°; *i.e.* a duck can bend much less at the waist than the other birds mentioned, and you have only to watch ducks on the wing to see that they are very poor steerers. This is but meagre evidence, and, at present, I have not the means of collecting more. Still, as far as it goes, it seems to show that suppleness of waist goes along with the power of swerving rapidly, and, *a priori*, it seems extremely improbable that such a highly acrobatic feat should be performed without calling into play every power that is available. Direct observation can, I fear, afford little help, since the feathers obscure any slight bend in the back. But the habit that many birds have—it can be easily seen in the case of gulls—of turning their heads in the direction in which they wish to go, suggests that it may be by bending the vertebral column at a point where it would be more effective, that they make their turns, just as a skater changes edge and flies off on an opposite curve by swaying the weight of his shoulders across to one side or the other, a change of balance effected by a bend sideways at the waist. It is certain that birds do not depend entirely on movements of the head or neck, since gulls, for instance, may occasionally be seen to turn to the left while looking to the right and *vice versa*, a point which may be made out from instantaneous photographs. I cannot help thinking, then, that a bird avails itself of the suppleness of its waist to alter its balance when it wishes to turn. Whether this is the sole means, or whether at the same time the wings are worked unequally so as to conduce to the same end is difficult to decide. I may add that I have found the required muscles at the waist considerably developed. F. W. Headley.

Haileybury, Hertford, July 6.

Remarkable Hailstones.

On Saturday afternoon, July 9, a very violent storm burst over Harrogate and its neighbourhood, accompanied by remarkably loud thunder and most brilliant and almost continuous lightning.

At first a little rain fell, but it was soon mixed with small hailstones about the size of peas of the usual form. These were quickly followed by hemispheres of the size and character indicated in Fig. C. After a few minutes they rapidly grew to the size of those shown in Figs. A and B, which are drawn very carefully to actual scale. Most were flattened oval discs, as shown in the two drawings, which exhibit top and side view of one hailstone. I went out myself and measured a good

number while they were falling by putting them on a sheet of paper and marking their maximum and minimum diameters. These large stones usually had an opaque spherulitic-like nucleus, followed by two, three, and even a trace of a fourth clear ice shell intervening with opaque ice. Then followed a broad band of clear ice with a few radiating air cavities, finally enclosed in a mass of white granular feathery ice. The number of alternating laminæ seemed to be irregular, and must have varied with that of the different vapour strata traversed by each nucleus. The origin of the type (Fig. A from Fig. C) is very obvious. The quantity that fell was enormous, so that a lawn badly kept was entirely white, with the exception of the longer blades of grass that projected. The damage done in the near neighbourhood must amount to some thousands of pounds, and very few are the houses in this town that escaped without windows being broken. I did not time the duration of the fall, but I think it was about an hour.

5, Princes Square, Harrogate. H. J. Johnston-Lavis.
July 12.

A Substitute for Ampère's Swimmer.

I have long been dissatisfied with the rules commonly given in order to enable the relation between the direction of a current and that assumed by a magnet in its neighbourhood to be readily brought to mind. It is a small matter, but it causes a great deal of worry to many a student. The vagaries of Ampère's swimmer are "past the wit of man." Prof. Jameson's rule is not bad, but is not really easy to remember; the corkscrew is good, provided that you have a little time to think about it; but I have felt all along that it ought to be possible to devise something simpler than any of these. May I suggest that the following may perhaps be found useful?

If a pen be held in the right hand in the usual way, the penholder may be taken to represent the wire, and the direction of the flow of ink (that is, towards the point of the pen) the direction of the current; if, then, the thumb be stretched a little across the penholder it will represent the magnet, and the thumb-nail its marked or north-seeking pole. The hand may, of course, be twisted round into any position to represent any actual case. The same relation may be still more simply borne in mind by dispensing with the penholder, and merely laying the thumb across the forefinger of the right hand; either of these will then represent the current (flowing towards the finger, or the thumb-nail, as the case may be), the other the magnet.

Whether this is novel I do not know; it is so as far at I am concerned; but I think it is useful. Alfred Daniell.

Advocates' Library, Edinburgh, July 13.

The Jelly-fish of Lake Urumiah.

In Mr. Curzon's recently-published work "Persia and the Persian Question" (vol. i. p. 533), he writes as follows:—"When the wind blows on Lake Urumiah, sheets of saline foam are seen scudding along the surface, and the salt is left upon the shore in a solid efflorescence, sometimes several inches thick. No fish or molluscs live in the waters, whose sole living contents are a species of *small jelly-fish*, which sustain the swans and wild fowl that are occasionally seen."

When Captain F. R. Maunsell read his interesting paper on Kurdistan to the Royal Geographical Society in June last, I asked him whether he could give me any further information respecting this so-called "jelly-fish," to which he was kind enough to reply as follows:—"In reply to your inquiries regarding the existence of a jelly-fish in Lake Urmia, I have been going through my notes, and find that I visited the lake on July 20 at its west shore, not far from the town of Urmia. I bathed in the lake and found the jelly-fish in great numbers along the shores where the water was shallow. It was only about half an inch in diameter, of a greenish-white, almost colourless, with a small black centre. There are said to be no fish or other living creatures in the water, and I did not see any. As you probably know, the lake is extremely salt, more so than the Dead Sea. The specific gravity is given as 1·155, with 21·4 per cent. of salt. The lake is 4,100 feet above the sea level, and has no outlet. There is a British Consul in Tabriz, which is not far from the east shore of the lake, who might obtain a specimen, and would be able to ensure its getting home safely better than any one else. The lake is very shallow compared with its great size, nowhere being more than from thirty to forty feet in depth."

The only instance of a "jelly-fish" or Medusa as yet known to inhabit an inland sea is that of the *Limnocnida tanganjicæ*, recently described by Mr. R. T. Günther (Ann. and Mag. N. H. ser. 6, xi. p. 274 (1893)). It would be therefore of great interest to obtain specimens of the "jelly-fish" of Lake Urumiah and ascertain what it really is.

3, Hanover-square, W., July 17. P. L. Sclater.

Racial Dwarfs in the Pyrenees.

Being on the Riviera when I received Nature of January 26 with Mr. Haliburton's letter on the above subject, I proposed to act on his suggestion, and, on my way back to England, to explore the region indicated. To ensure, however, that the proposed exploration should not be a wild-goose chase, I first entered into communication with all the British consuls and French savants likely to have special knowledge of the subject, and more particularly with M. Cartailhac, director of *l'Anthropologie*, and who resides at Toulouse, "within little more than a half-day's journey" from the valleys named by Mr. Haliburton. I was favoured with interesting replies from all those to whom I had written with the single exception, very curiously, of our consul at Barcelona, a letter from whom you published, and who appears to have been Mr. Haliburton's chief authority. As to the replies I received, I need only say that they so strongly negatived the assertion of there being "racial dwarfs," though admitting that there are "certains goitreux de petite taille," in the Pyrenean valleys, that I did not think it worth while to make the proposed journey. And as Mr. Haliburton repeats, in the current *Asiatic Quarterly*, the assertions made in NATURE, I feel bound to state these facts, though I may say that I quite agree with him as to the probability of a former wide distribution of dwarf races, and should have found Pyrenean dwarfs, had they been discoverable, in most interesting relations to the Ligurian giants, whose caves I had been exploring at Baoussé Roussé—the "Red Rocks" of Grimaldi.

Athenæum Club, July 10. J. S. STUART-GLENNIE.

THE NOTTINGHAM MEETING OF THE BRITISH ASSOCIATION.

THE forthcoming meeting of the British Association in Nottingham recalls the year 1866, when the present Mr. Justice Grove presided over the meeting in the town, and delivered his epoch-making address. Although this was the only meeting held in Nottingham, national conferences and associations of all kinds are constantly gathering in this very convenient, healthy, and picturesque centre; the inhabitants are therefore accustomed to the entertainment of guests. The public buildings will also be found to offer special facilities for the usual work of the British Association.

The University College, a large building almost central in position, has naturally been allotted to the meeting of the various sections. The lecture-theatres and class-rooms of the College provide accommodation for all the sections with the exception of two, and these will gather in commodious rooms in the immediate vicinity.

The various laboratories of the College are to be devoted to the exhibition of scientific apparatus and diagrams, some of which will be used during the meeting for the illustration of papers in the sections; and since these laboratories are very convenient for the purpose and are in direct communication with the sectional meeting-rooms, it is hoped that authors of papers will be induced to bestow special attention to the illustration of their papers, as the illustrative matter will be permanently on view throughout the meeting.

The Corporation of Nottingham not only grants the use of the University College, but also gives permission for the Castle Museum to be used for the conversaziones, and throws open the Exchange as a luncheon hall, with smoking-room and ladies' room as adjuncts. The large luncheon room thus provided will be supplemented by another large and convenient room in the University College.

The large hall at the Mechanics' Institution will be fitted as the reception-room with all the usual conveniences, the Albert Hall being reserved for the popular lectures, the president's address, and for a special concert to be given on Saturday evening by the Sacred Harmonic Society of the town.

It will be found on reference to a local map that not only are these various buildings easy to find, but that they lie most conveniently within range of one another, the extreme distance not exceeding a walk of five minutes.

The inhabitants of Nottingham are quite alive to the duties of hospitality, and not only will the officials and working members of the Association receive entertainment in private houses, but the clubs of the town are also throwing open their doors with one consent. A list of hotel and lodging accommodation is nearly ready for issue.

The local excursions include visits to the Dukeries, Charnwood Forest, Lincoln, Belvoir Castle, and Derbyshire; and, in connection with these visits, hospitality has been offered by the Duke of Portland, the Duke of Newcastle, the Duke of Rutland, and the Bishop of Southwell. Many other offers of hospitality are expected. Important works in the town and neighbourhood will also be open for inspection.

The local programme and excursion handbooks are in an advanced stage of preparation. These will serve as guides to the public buildings used for the meetings and indicate the hotels and lodgings, and the routes followed in the various excursions; they will also give information concerning the natural history of the district.

The work of the local committee would be greatly facilitated if all those who intend to be present or to take part in the meeting would communicate with the local secretaries, Guildhall, Nottingham, as soon as possible.

Without unduly anticipating the information which will be found in the local programme and publications, enough has been said to indicate that the local committee are actively preparing for the reception and entertainment of the members of the Association; and it is proposed next week to give some statement of the more serious work which will engage the attention of the general meeting and of the sections.

FRANK CLOWES.

THE GREAT DROUGHT OF 1893.

THE draught of 1893 will unquestionably take its place among the recorded events of history, if regard be had to its intensity, the length of time during which it has lasted, and the wide extent of the earth's surface it has overspread. Treating the British Islands as a whole, the drought may be considered as embracing by much the greater part of the country for the fifteen weeks beginning with March 5. But while copious rains have fallen during the past few weeks in many places, it may be regarded as continued to near the present time in many of the more important agricultural districts in the south.

The drought was most severely felt in the southern division of England, and least in the north of Scotland. Over Scotland, England, and Ireland it increased in intensity, with pretty uniform regularity, from north to south. Thus the deficiency in percentages from the average rainfall of that portion of the year was 30 at Lairg and 59 in Berwickshire; 59 at Penrith, and 90 at Dungeness and Falmouth, and 38 at Londonderry and 67 at Waterford. The least deficiency at any of the stations of the *Weekly Weather Report* was 1 at Glencarron, in Ross-shire, and the greatest at Dungeness and Falmouth, as stated above. At Glencarron the amount of the rainfall was 16·91 inches, whereas it was only 0·60 inch at Dungeness, 0·77 inch in London, 0·92 inch in Scilly, and 0·94 inch at Falmouth. At places south of a line drawn from Cambridge to Scilly less than a fourth part of the average rainfall of these fifteen weeks was collected, and consequently over this large district the effects of the drought have been most disastrous to agriculture and horticulture, the hay crop, for example, being in many places a complete failure. It was altogether a unique experience, in travelling in June from London to Scotland, to mark the great and steady improvement in the condition of the crops in the northward journey.

During the period the type of weather prevailing was eminently anticyclonic, with the appearance, ever and anon, in localities more or less restricted, of small satellite cyclones with their attendant thunderstorms and rains. Hence the remarkably sporadic character of much of the rainfall, of which the most remarkable instance was a rainfall of 1·19 inch at Parsonstown on June 10 and no rain whatever at any other of the telegraph stations of the Meteorological Office in this country. Heavy local rains of this type, with downpours of an inch or upwards, were recorded on May 17, 18, 20, and 21, and June 10. It is also to be noted that many thunderstorms occurred during the period unaccompanied with rain, just as happened generally in the east of Scotland in June 1887, on the day of the Queen's Jubilee; and frequently large drops of rain fell, quite insufficient even to wet the ground, and scattered over narrow paths of inconsiderable length. Very heavy rains occurred over the eastern districts of Scotland, practically terminating the drought there, on June 22 and 23, when on these two days 4·20 inches fell at the North Esk Reservoir on the Pentland Hills, 3·32 inches at Roslin, 2·21 inches at Aberdeen, 2·06 inches at Logie Coldstone, near Ballater, and nearly two inches at many places, whilst generally in the west little and at many places no rain fell at all.

Temperature was phenomenally and almost continuously high in March, April, May, and June, specially as regards the first three of these months. Thus, for London the mean of the three months was 4°·3 above the mean of the previous 130 years; and in Edinburgh 3°·3. The only springs since 1763 with a mean temperature exceeding that of 1893 were for London, 1811 and 1794, which were respectively 5°·2 and 4°·3 above the average; and for Edinburgh, 1779 and 1781, which exceeded the mean by 4°·0 and 3°·8. It is highly interesting to note that large as these figures are, the Ben Nevis figures far exceed them, the mean temperature at this high-level observatory for March, April, and May last being 6°·6 above the mean of these months, a result due to the prevailing anticyclones, which so frequently are attended there with abnormally high temperatures.

The drought has also extended over nearly the whole of Europe, large portions of Canada, the United States, and other parts of the globe. In the north of Italy no living person recollects to have seen the Italian Lakes so low, and the southern Alps so greatly denuded of their snow covering. It is estimated that over the wheat-growing countries of the world this valuable crop will be to no inconsiderable extent under the average. On the other hand, in other parts of the world the rainfall has been exceptionally heavy, and followed with widespread disastrous floods, as in the cotton districts of the United States, and in Queensland.

In London, the total amount of rain that fell during the 110 days from March 4 to June 22 was 0·77 inch. Mr. Symons, our best authority on the question of droughts, enumerates eight droughts which have been recorded during the present century. Of these the longest continued was 105 days, from March 11 to June 23, 1844; and thus the drought of the present year is the greatest in the British Islands authenticated by meteorological records.

NICOLAS IVANOVICH LOBATCHEFSKY.

NICOLAS IVANOVICH LOBATCHEFSKY, the founder of Non-Euclidean Geometry, was born on November 2, 1793.

A student, and subsequently professor at Kasan, the Physico-Mathematical Society of that interesting University have determined to celebrate the centenary of his birth by founding an International prize for Mathematical, and in particular, for Geometrical work bearing upon the late-born but remarkable branch of mathematical science and philosophy which owes its existence to Lobatchefsy's genius and has earned for him the title of the Copernicus of Geometry.

A committee including the names of Tchebyche, Poincaré, Hermite, Darboux, Klein, Sophus Lie, Lindemann, Cayley, Beltrami, Newcomb, Mittag-Leffler, and over a hundred other notabilities of the mathematical world in both hemispheres, has been appointed to assist in carrying out the plan.

At this time of day it would he superfluous to dilate on the pre-eminent claims to honourable recognition of one who has played a principal part in reconstituting the basis of geometrical thought and realised his ideas in a series of memoirs with a thoroughness and precision which Gauss in 1846 characterised as the work of "a true geometer."

Any English mathematician (and it is to be hoped there will be many) desirous of co-operating in erecting this monument (if it may be so called) to the memory of a great scientific reformer, may do so by forwarding a subscription addressed to Prof. Vassilief, President of the Physico-Mathematical Society, University of Kasan.

NOTES.

WE greatly regret to record the death of Dr. John Rae, F.R.S., at the age of eighty-one. It was he who, in 1854, collected relics of the ill-fated Franklin expedition in the *Erebus* and *Terror*.

AMONG the Civil List pensions granted during the year ending June 20, 1893, we note one of £75 to Mrs. Dittmar, in consideration of the services to chemical science rendered by her late husband, Prof. William Dittmar, F.R.S., and one of £50 to Mrs. T. Wolstenholme, in consideration of the merits of her husband, the late Rev. Joseph Wolstenholme, as a mathematician, and of her straitened circumstances.

FOR the convenience of those who wish to be present at the Rothamsted celebration on Saturday next, a special train will leave St. Pancras for Harpenden at 2.2 p.m., returning at 5 p.m. In connection with the celebrations at Rothamsted, it is interesting to recall the circumstance that in the early part of the present century the signal services rendered by Francis, Duke of Bedford, to the theory and practice of agriculture were recognised by the erection, in Russell Square, of a colossal statue to his memory. The scheme, in the first instance, was initiated by Sir Joseph Banks, then president of the Royal Society, the first meeting on the subject being held at his house in Soho Square. Subscriptions were solicited from the various agricultural societies existing at the time, and from private individuals, and these flowed in with many expressions of approval of the object in view. The statue and its pedestal, the latter emblematical of the art of husbandry, were designed by Richard Westmacott, who received the sum of £6000 for the work, each subscriber receiving an engraving of the design. An inscription records that the statue to the Duke was erected by his fellow labourers in the field of agricultural improvement in gratitude for his unwearied endeavours to improve the theory and practice of agriculture.

THE French Association for the Advancement of Science will hold its annual meeting from August 3 to August 13, at Besancon, under the presidency of Dr. Bouchard. The subjects for discussion in different sections are the mechanical traction of tramways, the local records from which a forecast of the weather at a given place can be made, the *rôle* of humus, works of commerce, and the administrative measures necessary to prevent the use of unfit articles of food.

THE death is announced of Mr. Walter White, who for upwards of forty years served the Royal Society, first in the capacity of clerk and afterwards of assistant secretary and Librarian. Mr. White retired from the latter post in 1885, and has from that time received a pension from the society. His bent was literary rather than scientific, and he was the author of several books of holiday travel written in a pleasant style and in that correct English upon which he always prided himself. Mr. White died on Friday last, in the eighty-third year of his age.

THE annual congress of the British Institute of Public Health will be held at Edinburgh from July 27 to August 1, under the presidency of Dr. Henry D. Littlejohn and the auspices of the Lord Provost and Corporation of Edinburgh.

THE Société Belge de Géologie et d'Hydrologie has arranged an excursion of some interest for August 4 to 9, under the direction of M. E. Dupont, the special object being to study the hydrology of the district around Dinant, Namur, Rochefort, Madave, &c. The springs and surface-streams will be examined, and also the famous Grotte de Han. Attention will also be paid to other physical features of the districts, including the formation of valley-terraces and the origin of the loam on the plateaux.

THE annual exhibition of the Photographic Society of Great Britain will be held at the Gallery of the Royal Society of Painters in Water-Colours, Pall Mall, from September 25 to November 15. It will be opened by a reception held by the President, Capt. Abney. The last day for receiving pictures is September 11.

THE Aspatria Agricultural College, which has been rebuilt and greatly enlarged, was opened on July 21 by the Mayor of Carlisle, before a large and representative gathering.

A STATUE of Claude Chappe, the inventor of the system of semaphore signalling, has recently been erected on the Boulevard Saint-Germain, Paris.

THE Société Industrielle de Mulhouse has issued its programme of prizes to be awarded in 1894. Prizes will be given for works on the constitution of various colouring matters, mordants, dyes, the fixing of colours, areometry, drugs, bleaching, actinometry, and other subjects. In mechanical arts the prize-subjects relate to building construction, steam engines, motors, spinning and weaving, electric motors, and the comparative advantages of gas and electricity for lighting purposes. There are also prizes for subjects of natural history and agriculture, commerce, statistical and historical geography, and the fine arts. The prizes are open to persons of all nationalities. Competitors should send in their memoirs, plans, and specimens, marked with a pseudonym or motto before February 15, 1894, to the President of the Society. The same pseudonym or motto, with the full name of the sender, must be forwarded under separate cover at the same time. A detailed programme of subjects for which prizes will be awarded, can be obtainec by application to the Secretary of the Society, Mulhouse, Alsace.

WHEN it was resolved last January "That it is desirable that the eminent services of the late Sir Richard Owen in the advancement of the knowledge of the sciences of anatomy, zoology, and palæontology should be commemorated by some suitable memorial," it was confidently expected that there would be a generous response to the appeal for funds. A large number of circulars were sent out, yet the list published in June contains the names of less than 300 contributors. The donations then amounted to £935, and the amount promised has even now only reached £1000, whereas the committee hoped to obtain at least twice that sum. For those who have come orward there is nothing but praise; the cause of complaint lies in the paucity of subscribers. Only 300 admirers of Owen can be found desirous of giving concrete expression to their feelings of regard. The fact is humiliating, and, for the sake of British science, we trust it will soon be altered. Of Sir Richard Owen it can truly be said, that among students of science "Many shall commend his understanding; and as long as the world endureth, it shall not be blotted out; his memorial shall not depart away, and his name shall live from generation to generation." But Owen's greatness should not only be appreciated by men of science, it should be made known to the world by means of a monument. As a mark of respect to their master and an act of duty, all naturalists should add a stone to his cairn.

ONE of the conclusions arrived at in 1888 by the Commission appointed to investigate the action of light on water colours, was that "every pigment is permanent when exposed to light '*in vacuo*,' and this indicates the direction in which experiments should be made for the preservation of water-colour drawings." Actuated by this expression of opinion, Mr. W. S. Simpson has devised a simple and effective means whereby works of art can be isolated from the deteriorating effects of air and moisture. The picture which it is desired to preserve is placed face downwards in a shallow rectangular tray having a clear glass bottom, and is then covered at the back. The chamber thus formed is afterwards exhausted by means of a Spregnel pump, and hermetically sealed. Assuming that no leakage occurs, and that light has no intrinsic action upon pigment, the picture will be preserved in all its pristine beauty until the crack of doom. To test for leakage, a small manometer, constructed on the principle of the aneroid barometer, can be fixed to each isolated picture. Mr. Simpson's idea is a good one, and it possesses the inestimable advantage of being applicable to any picture, for all that is required is to take the picture from its frame and fit it into an airtight chamber of the same size before replacing it. Should the vacuum not maintain its integrity, the manometer will indicate its imperfections, and the chamber can easily be exhausted again. It appears, therefore, that the method has great possibilities before it.

WITH regard to the statement made by Mr. E. Douglas Archibald in our issue of May 25, that the highest rainfall in twenty-four hours was 40·8 inches, registered at Chirapunji, in the Khasi hills, a correspondent writes to the *Ceylon Observer* as follows:—"If the *Indian Planters' Gazette* of 28 Jan., 1893, is correct, the following paragraph establishes a still higher record. On page 59 one reads: 'Our Dera Doon correspondent writes on January 24, 1893: last night we had 48 inches of rain, and all the hills are covered with snow. It is still raining.'" For this to have any scientific value, however, it must be known who were the observers, and by what means the rainfall was gauged.

THE duration and form of temperature waves as they occur at Trieste has been studied by Herr Ed. Mazelle, and described in a recent communication to the Vienna Academy. Daily records during the period from 1871 to 1890 show a mean wave length of 4·23 days. The longest waves occurred in winter and summer, the shortest in spring and autumn at Trieste, in marked contrast to Central Europe, where the reverse occurs. The mean duration of increase of temperature was always longer than that of fall of temperature, in the proportion of 2·39 to 1·84. For dull days both the periodic and the aperiodic diurnal variation were of less extent, but both the maxima and minima of temperature occurred earlier in the day. The variability of mean daily temperatures was different for different parts of the year, showing maxima in January and July, and minima in September and April. The occurrence of the first day of frost was found to vary between wider limits than that of the last frost.

THE German Meteorological Office has issued a volume containing the results of rainfall observations for the year 1891, together with a circular stating that the number of meteorological stations has so greatly increased as to make it advisable to publish five volumes yearly instead of one, two of which will be devoted to the magnetical and meteorological observations made at the Observatory at Potsdam. The number of rain stations has increased from 35 to 1425 since the establishment of the office in the year 1847. In addition to the usual monthly and yearly summaries, the greatest amounts which have fallen in short intervals are given for a large number of stations. These values show clearly how the intensity of the fall decreases with the duration, and that erroneous ideas may be obtained by estimating the hourly fall from that of a shorter period, as is sometimes done. The greatest fall during five minutes in the year 1891 amounted to ·15 inch per minute, during thirty minutes to ·08 inch per minute, and during one hour to ·04 inch per minute. The greatest fall registered in any one day was 4·3 inches on the May 26; a fall of 4·2 inches was also recorded on July 21.

Some idea may be formed of the rate of increase of the known species of fungi from the fact that, in a recent issue of the Proceedings of the Philadelphia Academy of Sciences, MM. Ellis and Everhart describe no less than 149 new species from North America. Of these 53 belong to the Pyrenomycetes, 24 to the Discomycetes, 11 to the Uredineæ, 2 to the Ustilagineæ, 46 to the Sphæropsideæ, 13 to the Hyphomycetes.

A flora of Donegal, by Mr. H. Chichester Hart, is about to be published. Until recent years the north-west of Ireland had been greatly neglected by botanists, and the publication is likely, therefore, to be of much interest.

The first part of MM. Rouy and Foucaud's "Flore de France" is announced to appear in August. The geographical area of the work includes, in addition to France proper, also Alsace, Lorraine, and Corsica; and there will be comprised a bibliography and a list of botanists who have contributed to our knowledge of the flora of France. The first volume of M. Bounier's "Florede la France," published under the auspices of the Ministry of Public Instruction, is expected to appear in the spring of 1894.

Two recent numbers of the *Botanisches Centralblatt* (vol. liv. nos. 12 and 13) are largely occupied by a review by Dr. Otto Kuntze of the discussion on botanical nomenclature since the publication of his "Revisio generum plantarum" in 1891.

Mr. Mark Stirrup has just published further information as to the occurrence of boulders in the coal measures of Lancashire (Trans. Manchester Geol. Soc., vol. xxii. p. 321). Most of the boulders hitherto recorded are of quartzite; some of those here described are of crystalline rock. Petrographical notes are given by Prof. Bonney. Mr. Stirrup also prints a letter from Prof. E. Orton relating to the occurrence of boulders of vein-quartz—not quartzite—in the coal measures of Ohio (see also *Amer. Journ. Sci.*, July 1892).

Boulders have been recently described from the Kulm beds of the Frankenwald, by E. Kalkowsky (*Zeitsch. Deutsch. geol. Gesell.* 1893, p. 69), who thinks that they indicate glacial action. This explanation is not satisfactory for the English boulders in coal measures, the origin of which is still unknown.

Prof. Frank D. Adams has published an interesting description of the Norian Rock of Canada ("Ueber das Norian oder Ober-Laurentian von Canada" extracted from *N. Jahrb.*, Beilagebd. viii., 1893, pp. 419–498). This forms a thesis for the doctor's degree at the University of Heidelberg. The Norian rocks consist mainly of "anorthosite," in which plagioclase is the chief constituent, ferro-magnesian silicates being scarce or absent. These rocks are intrusive in the Grenville series—the upper division of the Lower Laurentian of Logan, who regarded the Norian series as Upper Laurentian. Prof. Adams shows that the anorthosites occur near the eastern edge of the great Archæan platform of Canada. He compares this with the distribution of modern volcanoes along the edges of the Continents. Some of the anorthosite masses are of great extent; that of the Saguenay district covers an area of nearly 6000 sq. miles, that of Morin 1000 sq. miles. These results may be compared with the conclusions already published by Prof. A. C. Lawson, that the Laurentian gneisses of the Rainy Lake region are intrusive in the so-called "Huronian" of that area, rocks which were previously considered to be later than the Laurentian. Prof. Adams's paper contains a map of the Archæan area of Canada and a full bibliography.

Experiments on the value of ammonia vapour as a disinfectant have been recently made by Rigler (*Centralblatt fur Bakteriologie*, vol. xiii. No. 20). The organisms employed were Koch's cholera bacillus, the typhoid bacillus, Loeffler's diphtheria bacillus, and the spores and bacilli of anthrax. Threads soaked in broth-cultures of these various organisms were freely exposed in a room filled with ammonia vapour, whilst other threads were wrapped up in dry and damp cloths respectively before being submitted to the vapour, and in every case control threads were simultaneously exposed to air. It was found that cholera bacilli were killed after two hours' exposure in the ammonia room, whether free or enclosed in dry cloths, whilst twice that time elapsed before they succumbed in moist surroundings. In ordinary air they were destroyed in three hours, but they were alive after two days when kept in *moist* cloths. Two hours' exposure in the ammonia vapour, whether freely exposed or in dry wrappers, sufficed to destroy the typhoid bacilli, but in moist surroundings six hours was necessary, whilst twenty-four hours' contact with ordinary air produced no effect upon them. Anthrax bacilli succumbed in three hours in the ammonia room, but their existence was prolonged for five hours when wrapped in dry cloths, whilst whether in dry or moist surroundings a day's exposure in ordinary air left them untouched. The spores, however, were only destroyed after being eight hours in the ammonia vapour, and in ordinary air were unaffected. Diphtheria bacilli, whilst surviving twenty-four hours' contact with ordinary air, were annihilated in four hours by the ammonia vapour, the nature of their environment making no difference in their powers of resistance. In consequence of its efficacy, cheapness, and harmless character as regards furniture and clothing, Rigler recommends ammonia vapour as an important means of disinfection.

The metric measures are in general use in Russia in scientific literature. They have also been adopted by the Mining Administration in all its publications, while the railway and water communications engineers are using the decimal divisions of the Russian *sagène* (7 English feet). Prof. Petrushevskiy, who has advocated since 1868 the adoption of metrical measures, now gives in the Journal of the Russian Chemical and Physical Society his scheme of metric measures, as near as possible to the present Russian measures, so as to make them easily acceptable to the population. It must be said that the general use of the *schoty* (reckoners, made of wires with ten beads on each wire, and used by all peasants, as well as by primary schools for the teaching of arithmetic) and the decimal division of money would greatly facilitate the acceptance of the metric system in Russia. The change is also facilitated by the fact that the Russian *sagène* is very nearly equal to 2 metres, the *versta* is nearly equal to the kilometre, and the *desiatina* differs but little from the hectare. The system proposed by Prof. Petrushevskiy is both plain and at once intelligible. It is that the *new sagène* shall be equal to the double metre (0·9374 of the present measure) and that a *half sagène* equal to one metre shall be divided into 20 *vershoks* (5 cm. are equal to 1·1248 of the present *vershok*). Also that the new *versta* shall be equal to the kilometre (0·9374 of the present *versta*), the *small desiatina* to the hectare and to 0·9153 of the present *desiatina;* the *big cube* to 10 cubic metres and to 1·0296 cubic *sagènes;* the *small vedro* to 10 litres and to nearly four-fifths (0·0131) of the present *vedro;* the *big measure* (1000 litres) to nearly five (4·795) *tchetveriks;* and finally the *big pound* (500 grammes) equal to 1·221 Russian pounds. It will be seen that the whole system is consistent with the spirit of the metric system, which fully admits of measures obtained from the multiplication of the metric ones by 2, 5, or 10, or from their divisions by the same members.

SIGNOR RICCARDO ARNÒ has communicated to the Reale Accademia delle Scienze di Torino his results obtained during an investigation of the diathermanous power of ebonite for heat waves of various lengths. He employed six different sources of light, whose radiant heat was sent through plates of ebonite of thicknesses varying from 0·12 to 0·52 mm. The thinnest of these absorbed 25 per cent of the heat radiated from an incandescent lamp, whose luminous heat rays were cut off by a thick plate of glass. When the source of light was very bright, this film was found to transmit a small portion of the visible red rays. Sixty-nine per cent. of the dark rays from the smoked surface of a Leslie cube containing boiling water were absorbed by the thinnest film, and 88 per cent. by the two others, thus showing that ebonite is less transparent for dark heat rays of low refrangibility than for those more approaching the visible spectrum. The greatest transparency was shown for the dark heat rays on the border of the luminous spectrum. The successive substitution of a hot iron plate, a glowing platinum wire, a Locatelli lamp, and an incandescent lamp for the Leslie cube brought about a steady increase of transmitting power in all the specimens of ebonite.

PROFS. BARTOLI AND STRACCIATI have brought their eight years' work on the specific heat of water to a close by reducing the values obtained with the nitrogen thermometer as a standard to the scale of the hydrogen thermometer. The corrected formula for the quantity of heat necessary to raise the temperature of 1 gramme of water from 0° to t° C., where t is less than + 31, as given in the *Rendiconti* of the Reale Istituto Lombardo, is

$$1{\cdot}006880t - 278 \times 10^{-6}t^2 - 205 \times 10^{-8}t^3 + 25375 \times 10^{-11}t^4 - 26 \times 10^{-10}t^5.$$

This formula, obtained by eight different methods and several thousand determinations, appears capable of serving as a reliable basis for calorimetrical science.

IN a further note contributed to the Academy of Lincei, Augusto Righi continues the description of experiments he has conducted with electrical oscillations of very small wave-length (see NATURE, June 22, 1893). The oscillator employed consists of two small metal spheres surrounded with oil and held by two rods of ebonite. These two spheres are placed between the discharging rods of a large Holtz electrical machine. With spheres 4 cm. in diameter the wave-length of the radiation obtained was 20 cm., while with spheres of 1·3 cm. diameter the wave-length was about 7 cm. The resonator employed was of a novel form and was made by taking a rectangular piece of ordinary silvered glass of such a size that its breadth was equal to the length of the resonator required. The varnish was then dissolved off the back of the silver, and a line drawn through the silver by means of a diamond, so as to divide the strip of silver into two equal parts, and form a spark gap. By this means a spark gap was obtained, having a breadth of between one and two thousandths of a millimetre. For radiation having a wave-length of 7·5 cm. the resonator was composed of a strip of silver 3·9 cm. long and 0·2 cm. broad. Although with these small wave-lengths the sparks cease to be visible when the distance between the oscillator and resonator is a metre, by placing a parabolic metallic reflector behind the resonator the sparks were visible at a distance of six metres from the oscillator. Using the above form of apparatus the author has repeated the experiments of Lodge and Howard and others on the reflection and refraction of electrical waves, he has also succeeded in producing interference between the rays reflected from two mirrors inclined at a slight angle (Fresnel's experiment). An interesting set of measurements of the transparency of various dielectrics gave (amongst others) the following results:—Ebonite, paraffin, and rock salt are perfectly transparent. A plate of mica 1·7 mm. thick absorbs 10% of the radiation, while a plate of ordinary glass 8 mm. thick absorbs 37%, and a piece of quartz cut normally to the axis 8 mm. thick absorbs 40%.

WE have received the first part of "The Book of the Fair," by Mr. Hubert Howe Bancroft. It is grandiloquently described on the title-page as "An Historical and Descriptive Presentation of the World's Science, Art, and Industry, as viewed through the Columbian Exposition at Chicago in 1893. Designed to set forth the Display made by the Congress of Nations, of Human Achievement in Material Form, so as the more effectually to illustrate the Progress of Mankind in all the Departments of Civilised Life." The part of the book before us deals with great fairs of the past, and the history of Chicago, the object apparently being to make the story as long as possible. Both the text and illustrations are excellent.

A COLLECTION of meteorological tables, compiled by Dr. Arnold Guyot, was issued by the Smithsonian Institution in 1852. The fourth edition was published in 1884, and the work had then grown to a bulky tome of more than 700 pages. Upon a demand for a fifth edition, Prof. S. P. Langley decided to publish the tables in three parts: Meteorological Tables, Geographical Tables, and Physical Tables, each independent of the other, but the three forming a homogeneous series. The volume of meteorological tables is before us, and it is of far more handy dimensions than formerly. Everything appertaining to meteorological work appears to be contained therein, and the fact that the work comes from the Smithsonian Institution vouches for its excellence. Our attention has been directed to a slip on p. 248. In the list of meteorological stations in the British Isles given on that page we find printed "Richmond (*Greenwich Observatory*)," lat. 51° 29′ N., long. 0° 0′. The first word should be omitted in future editions, for Greenwich, and not Richmond, is obviously referred to.

NINETEEN charts of the "Isle of Wight and Solent Tides," from Portland Bill to the Owers, have been prepared by Mr. T. B. C. West and Mr. F. Howard Collins, and are published by Mr. J. D. Potter, Poultry, E.C. They show by means of arrows the direction of tidal streams at all hours, and, at some places, for half hours of the tides. The rates given are for spring tides, but those for neap and average tides can easily be estimated. The charts are excellently engraved from an Admiralty chart, and the arrows are placed in accordance with the information contained in the "Channel Pilot." They are issued in an extremely compact form, and to the yachtsman of the Isle of Wight district must prove invaluable.

"EVOLUTION AND RELIGION," by Mr. A. J. Dadson, has been published by Messrs. Swan, Sonnenschein and Co. The first three chapters of the book are concerned with the doctrine of evolution, and the remainder deal with theological matters, while the whole has been written with the laudable object of bringing about a reconciliation between religion and science. May the truth prevail.

Messrs. West, Newman, & Co., have just published a book by Mr. S. T. Dunn on the flora of South-West Surrey, including Dorking, Godalming, Farnham, and Haslemere. The last flora including this district was Brewer's, dated 1863. Another county flora is in preparation by Mr. W. H. Beeby. It need scarcely be said that Mr. Dunn's little book is not intended to take the place of these more complete floras, but it will serve as a portable field guide to visitors.

The sodium salt of the as yet little-known perchromic acid has been isolated by Dr. C. Häussermann in the state of well-defined crystals, and is described in a communication to the current number of the *Journal für Praktische Chemie*. The possibility of the existence of an acid-forming oxide of chromium higher than the trioxide CrO_3 has formed a subject of discussion for many years. It was long considered that the deep blue coloration produced upon adding hydrogen peroxide to a solution of chromic acid was due to the formation of the hydrate of a peroxide of chromium. Both the first observer of this interesting reaction, Barreswill, and Ascher in a subsequent memoir, considered the peroxide to possess the composition Cr_2O_7, corresponding to the heptoxide of manganese, Mn_2O_7 present in the permanganates. Fairley has since attributed to the blue compound the composition $CrO_6.3H_2O$. Latterly, however, Moissan has adduced evidence in support of the view that the substance is nothing more than a molecular compound of chromic anhydride with hydrogen peroxide, $CrO_3.H_2O_2$. The work of Häussermann is therefore particularly interesting as showing that, whatever may be the truth concerning the blue compound above referred to, a higher acid of chromium is capable of existence. Moreover, it is not without some significance that the formula of the anhydride derived by Häussermann from the analyses of his sodium salt coincides with that, CrO_6, attributed by Fairley to the oxide present in the blue compound. Häussermann finds that when sodium peroxide is added in small quantities at a time to chromic hydrate suspended in a small quantity of water and maintained at a low temperature by means of an ice bath, a somewhat violent reaction occurs, rendering constant agitation necessary; the chromic hydrate dissolves, a brownish-yellow solution being produced. When this liquid is allowed to stand undisturbed for a time in a cold room, brilliant brownish red, transparent, monoclinic crystals separate. These crystals are found upon analysis to possess the composition $Na_6Cr_2O_{15}.28H_2O$. They rapidly effloresce upon exposure to the air, falling to a brown powder. They lose the whole of their water of crystallisation when placed in a desiccator over oil of vitriol, or when heated to 100°. At a temperature of 170° they explode with some violence, leaving behind a quantity of sodium chromate mixed with sodium hydrate. The anhydrous salt is tolerably stable and is only very slowly attacked by cold water. Hot water, however, immediately decomposes it with formation of a solution of sodium chromate and sodium hydrate and liberation of three molecular equivalents of oxygen gas.

$$Na_6Cr_2O_{15} + H_2O = 2Na_2CrO_4 + 2NaOH + 3O_2.$$

Analyses of the anhydrous salt agree with the formula $Na_6Cr_2O_{15}$, indicating an anhydride of the composition Cr_2O_{12} or CrO_6. It is most interesting that, upon the addition of dilute sulphuric acid to the salt, the deep blue coloration above alluded to is at once produced, as if it were due to the formation of the free acid, the hydrate of CrO_6. In a few minutes oxygen commences to be evolved, and chromic sulphate is formed in the solution. Alkalies are practically without action upon the salt, which would thus appear to be stable in alkaline solution.

Notes from the Marine Biological Station, Plymouth.—Last week's captures include a colony of a tall (1½ ins.) variety of the Hydroid *Coryne vermicularis*, Hincks, the Polyzoan *Pedicellina echinata*, and the Tunicata *Phallusia mammillata* and *Ascidia depressa*. An incursion of the Cladocera *Podon* and *Evadne* has characterised the floating fauna; and with these have been taken Cirrhipede *Nauplii*, *Cyphonautes* larvæ, and countless numbers of minute *Obelia* medusæ. The following animals are now breeding:—The Cephalopod *Sepiola atlantica*, the Malacostraca *Chelura terebrans*, *Limnoria lignorum* and *Eupagurus Prideauxii*, and the Echinoderm *Echinus acutus*.

The additions to the Zoological Society's Gardens during the past week include two Great Eagle Owls (*Bubo maximus*), European, presented by Lord Hill; two Barbary Turtle Doves (*Turtur risorius* var.) from the Pescadore Islands, China, presented by Mr. Theodore A. W. Hance, C.M.Z.S.; three Giant Toads (*Bufo marinus*) from Brazil, presented by Mr. Adamson; a yellow-cheeked Lemur (*Lemur xanthomystax*) from Madagascar, a Banded Ichneumon (*Herpestes fasciatus*) from West Africa, deposited; a Black Ape (*Cynopithecus niger*) from the Celebes; two Black-headed Mynahs (*Temenuchus pagodarum*), two Manyar Weaver Birds (*Ploceus manyar*), two Red-headed Buntings (*Emberiza luteola*) from India, purchased; two Dominican Gulls (*Larus dominicus*) bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

The Discovery of the New Comet.—The new comet seems to have been noted by a number of observers before they had seen its discovery announced. Mr. Edgar Richards writes to us as follows in a letter dated July 13:—

"On Sunday last, the 9th inst., at 9.30 p.m., the members of the Astronomy Club, composed of several of the lady guests of the Cliff House, Minnewaska, N.Y., U.S.A., saw in the north-western heavens a most brilliant comet with well-defined nucleus and bright tail. The comet was in the constellation Lynx, and its tail extended towards the North Star. Its motion was very rapid in a south-westerly direction, and the tail was momentarily increasing in length as long as the comet was visible. The Club suffers from the disadvantage of not possessing a good telescope, so observations have to be made unassisted. No notice in the newspapers of such a comet having been seen and noted, the ladies were filled with enthusiasm to be, as they supposed, its first discoverers."

"Monday night the comet was found to be near the feet of the Great Bear, and much diminished in brilliancy, proving that it was rapidly receding from the earth."

It seems desirable, for the sake of cometary history, to give the following translation of a note by M. Tisserand in *Comptes Rendus*, No. 3.

"On the 10th July last, in the morning, I received a telegram from M. Quénisset, of the staff of the Juvisy Observatory, announcing that he had the previous night, the evening of the 9th July, discovered a bright comet, visible to the naked eye, whose approximate co-ordinates he gave. I at once transmitted a telegram to Kiel. The following morning, July 11, there came a telegram from Kiel, announcing that the comet had been seen on July 8 at Utah, U.S.A. by Mr. Rordame. It is therefore certain that Mr. Rordame has discovered the comet, but that M. Quénisset has announced it first. Perhaps it will be convenient to call it the Rordame-Quénisset comet; there are analogous precedents."

Comet Finlay (1886 VII.).—The following is the ephemeris of this comet for the present week:—

12h. *Paris Mean Time*.

1893.		R.A. (app.) h. m. s.		Decl. (app.) ° ′ ″

CHANGES IN THE SPECTRUM OF β LYRÆ.—At the Pulkova Observatory, the new spectroscope has been adapted to the large refractor, and among many of the stellar photographs already obtained several are of β Lyræ, the changes in which are described by Belopolsky in the June number of the *Memorie della Società degli Spettroscopisti Italiani*. The measures of position of the lines were made relatively to the solar lines by superposing a solar spectrum on that of the star. A general examination of the plates showed the following details, the most remarkable lines being D_3, 501·4$\mu\mu$, 492$\mu\mu$, F, 471$\mu\mu$, 448$\mu\mu$, 447$\mu\mu$. F consisted nearly always of two brilliant rays, one of which would disappear or become very dim, and between these could occasionally be seen a dark line; in the vicinity of F occasionally is seen also another dark line. The analysis of the changes in the bright F line indicates that its duplicity depends on one or both of the dark lines, or in other words, that we have here a case of superposition of the bright and dark lines. The period is nearly of 13 days' duration. At the principal minimum of the star, the bright F becomes single, the dark lines being situated one on the edge and the other alone. At the maximum, F becomes double, but the component on the violet side is very thin. At secondary minimum, F is double and symmetrical. Little change takes place at the following maximum, the component on the red side being a little thinner than the other; after this maximum it becomes a dark line.

With regard to the dark F line, M. Belopolsky says that this seems to consist of two, but it is seldom that they are separated; it is suggested that a second ray may mask the changes in wave length of the other, thus accounting for the irregular changes.

The Helium line undergoes two changes; sometimes it disappears altogether, while at other times it appears double. Its period of duplicity is put down as 7 days. The group 448-447$\mu\mu$ is defined as very complicated, and presents the same changes as the F lines, consisting of dark and bright lines and changing their positions like the components of the F lines. This paper is accompanied by a diagram showing the positions of the star in the curve of brightness at the time of exposure, and also by copies of several of the spectra.

THE VARIABLE STAR Y CYGNI.—Among recent papers on variable stars, that by Prof. N. C. Dunér on the elements of the variable star Y Cygni is of great importance. (*Kongl: Vetenskaps Akademiens Forhandlinger*, 1892, No. 7). This star is of the Algol type, and its variation is limited nearly exclusively to a small portion of its period during which it descends in a few hours to a minimum, to regain in about the same time its ordinary brightness. Since its discovery by Chandler in 1886, it has been very constantly observed, and it is perhaps on this account that Prof. Dunér can give such a complete story. Considering the odd and even minima separately, he deduces a formula which gives very small values for the residuals obtained from the observed minus calculated times, and to put it shortly he is led to the conclusion that the star Y Cygni consists of two stars of equal magnitude and brightness, moving in an elliptic orbit, the plane of which passes through the sun, and whose line of apsides makes an angle with the line of sight. The time of revolution is 2 days 23 hours, 54 minutes, 43·26 seconds. Prof. Dunér, at the latter end of this paper, gives the ephemeris and tables of interpolation of the times of the odd and even epochs in Paris mean time.

NEW DETERMINATION OF THE CONSTANT OF UNIVERSAL ATTRACTION.—A new and original method of determining the mass and density of the earth was described in our issue of July 13 (p. 251).

The following further information on the same subject is interesting. The first experiments gave for the value of K—the constant of gravitation—

$$K = 6{\cdot}80 \times 10^{-8}.$$

Determining the mass of the earth, by substituting this value of K in the formula

$$g\mu = K.\ \frac{\mu M}{R^2}$$

when M and R represent the mass and radius of the earth respectively, and where

$$g = 981 \text{ and } R = 6{\cdot}37 \times 10^8 \text{ centimetres,}$$

the value obtained was

$$M = 5{\cdot}85 \times 10^{27} \text{ grammes,}$$

whence the density of the earth was found to be

$$D = 5{\cdot}41.$$

We here enumerate the different values that we possess with regard to the earth density—

Plumb-line at	Schiehallien (Maskelyne and Playfair)	4·713
,,	Arthur's Seat (James)	5·316
Pendulum at	Mont Cenis (Carlini and Giulis)	4·94
,,	Harton Coal Pit (Airy)	6·565
Torsion-Balance	(Cavendish, 1798)	5·48
,,	(Reich, 1838)	5·49
,,	(Baily, 1843)	5·66
,,	(Cornu and Baille, 1872)	5·5 –5·56

THE CORONAL ATMOSPHERE OF THE SUN.—Prof. Janssen, in *Comptes Rendus*, No. 2, for July 10, communicates an interesting note on the history of facts which have demonstrated the existence of the coronal atmosphere of the sun.

VARIABLE STARS.—In the *Astronomical Journal*, No. 299, M. Paul Yendell publishes more observations of the maxima and minima of variable stars. Among some of those referred to are Y Ophiuchi, X Cygni, T Vulpecellæ, X, W, Y, and U Sagittarii.

GEOGRAPHICAL NOTES.

THE *Times* has received the following telegram from Dr. Nansen, dated Berlevaag, July 21. Berlevaag is about sixty miles west of Vardö, on the north coast of Norway:—"We are leaving Vardö for Yugor Strait (between Waigatz Island, south of Nova Zembla, and the coast of Russia), where thirty sledge dogs will be waiting for us. We then proceed along the Siberian coast eastward past Cape Chelyuskin to the Olenets river, near the Lena, where another twenty-six dogs will be waiting for us. We then turn northwards, and hope to reach the west coast of the New Siberian Islands in the end of August if the ice is not bad. The latest information about the ice conditions in that quarter is favourable. We then proceed direct northwards until we get fast in the ice. If we meet with new land we shall follow along its west coast northwards. When there is no more open water we shall allow the *Fram* to drift with the ice. Everything has gone on well up to the present. The *Fram* is a splendid strong ship and will stand the ice-pressure well. She is deeply laden with coal, but that is a drawback which will soon be remedied. The accounts of the ice in the White Sea and the Barents Sea are not favourable. There has been much ice, but hope it has now improved; the ice changes quickly. I have good hopes; if we only get through the Kara Sea in good time I feel certain the prospects of success are good.—FRIDTJOF NANSEN."

THE July number of the *Geographical Journal* commences the second volume. Amongst other papers of interest there is one of some importance on South-west Africa by Count Pfeil, who has taken a leading part in settling the interesting German colony at Windhoek, east of Walfisch Bay. Regarding Port Nolloth, he points out the curious fact that the great waggon traffic set up by the copper mines of Ookiep has led to the uprooting for fuel of all the little bushes which formed the sole vegetation of the country. The light soil deprived of its protection has changed into drifting sand, and there is no prospect of this artificial desert being redeemed by natural agencies.

IN the last number of the *Scottish Geographical Magazine* there is an abstract of an important paper by Prof. H. Wagner on the teaching of geography in Germany, which gives an admirable *résumé* of the growth to university rank of that study, the adequate recognition of which is confined to Germany, and the true proportions of which have never yet been realised in this country.

IN the *Asiatic Quarterly Review* Prof. Sayce shows that the term Sinaitic peninsula applied to the region between the Gulfs of Suez and Akaba is a misnomer; all the evidence available proving that Mount Sinai really stands somewhere in the ranges of Mount Seir, the exact site being still unknown.

SOME RECENT RESTORATIONS OF DINOSAURS.

IF palæontologists are apt to be discouraged by the apparent hopelessness of ever arriving at a satisfactory conclusion as to the structure and affinities of some of the fossil vertebrates with which they have to deal, they ought assuredly to take fresh confidence from the marvellous advance which has taken place of late years in our knowledge of the organisation of those huge extinct reptiles commonly known as Dinosaurs. It was, indeed, as far back as 1824 that the carnivorous genus *Megalosaurus* was first made known to us by Buckland, from specimens obtained in the Great Oolite of Oxford, while the following year saw the first announcement by Mantell of the now well-known *Iguanodon* from the Sussex Wealden. These early pioneers in this branch of palæontology necessarily had, however, but a faint conception of the real structure, and still less of the morphological importance of the group of reptiles whose former existence they were the first to reveal. It was long, indeed (in spite of the efforts of anatomists like Cuvier, Owen, and Huxley), before the riddle of the structure of the pelvis of the *Iguanodon* was solved, the final solution being given by Mr. J. W. Hulke in a paper read before the Geological Society on June 9, 1875, and published in the following year. The appearance of this paper may be said, indeed, to mark the commencement of the epoch of rapid advance in our knowledge of Dinosaurs, for only two years afterwards (1878) was issued the first of Prof. O. C. Marsh's important series of memoirs on the American Jurassic Dinosaurs, from which it appears that the true nature of the Iguanodont pelvis had been independently discovered in America. About the same time that the first of the American palæontologist's memoirs saw the light the scientific world was startled by Monsieur E. Dupont's announcement of the discovery of numerous entire skeletons of Iguanodons in fissures of the Belgian coal-fields. And this unexpected and fortuitous discovery enabled Monsieur L. Dollo to publish in April, 1883, the completely restored skeleton of one of these monsters in its natural attitude.

Although as far back as 1861, Sir R. Owen had described the greater portion of a Dinosaurian skeleton from the Dorsetshire Lias, M. Dollo's figure was the first complete restoration of the skeleton of a Dinosaur based on actual specimens. Scarcely, however, had this figure appeared when Prof. Marsh (August, 1883) gave us the restoration of the entire skeleton of an American Dinosaur (*Brontosaurus*), of still more stupendous bulk than the *Iguanodon*, and belonging to a group hitherto but very imperfectly understood. From that date till 1891 (although much important work on the group was being done) there seems, however, to have been a lull in the work of Dinosaurian restoration, no foreign worker having apparently made any attempts at further complete restorations of the skeletons of these reptiles. In the United States specimens both from the Jurassic and the newly explored Cretaceous strata were, however, steadily accumulating; and during that year Prof. Marsh published restorations of the skeletons of two forms, which for strangeness and uncouthness exceed the wildest flights of the imagination.

In glancing at some of the more striking features of these different Dinosaurian restorations, we may remind our readers that Dinosaurs may be divided into three main groups, of which the first is represented by the Brontosaur (Fig. 1), the second by the Megalosaur, of which an authentic restoration has but recently been published, while in the third we have two sub-groups, one of which is typified by the Iguanodon (Fig. 5), and the other by *Hypsirophus* (Fig. 3).

In the first, or crocodile-like group (Sauropsida), we have the least specialised forms (Fig. 1), all of which were habitually four-footed, and distinguished by their solid limb-bones, and the excavation of the sides of the bodies of most of their vertebræ by large cavities, which may have been filled with air in the living condition. The pelvis, as will be seen from our figure, is of a comparatively normal structure, with a relatively short anterior process to the upper bone or ilium,[1] and with the lower bones known as the pubis and ischium respectively inclined forwards and backwards after the crocodilian fashion. Our figure is taken from Prof. Marsh's restoration of 1883, in which the skull is imperfect, but in a later figure given by the Professor the head is fully restored, with the characteristic spoon-like teeth in position. In referring to this restoration Prof. Marsh observes that "the diminutive head will first attract attention, as it is smaller in proportion to the body than in any other reptile hitherto known. The neck was very long and flexible. The body was rather short. The legs and feet were massive, and the bones all solid. The tail was very long and powerful. The animal during life must have been nearly sixty feet in length, and about fifteen feet in height. Its probable weight was more than twenty tons. *Brontosaurus* was herbivorous in habit, and its food was probably aquatic plants or other succulent vegetation. The skeleton here represented was found in the Upper Jurassic, in Wyoming, west of the Rocky Mountain range."

We may add that the first known members of this group were discovered in British strata, the Cetiosaurus having been described from the great oolite by Owen, in 1842, and the *Pelorosaurus* by Mantell, in 1850, on the evidence of a stupendous humerus from the Wealden. The fragmentary and disassociated condition of the English specimens rendered it, however, quite impossible to refer with certainty the various teeth, vertebra, and limb-bones to their respective owners until we had the American skeletons as a standard for comparison, and even with that advantage we are not altogether clear on these points. There is, moreover, still some degree of doubt as to the right of some of the American forms to be separated generically from their European allies.

Till 1892 we had no fully authentic restoration of the skeleton of any of the larger members of the Carnivorous, or Megalosaurian group; but this want has been supplied by Prof. Marsh, from whose figures the accompanying illustration (Fig. 2) has been reproduced. It will be seen that, with the exception of the anterior vertebræ of the back, the skeleton is nearly complete; and since the missing vertebræ are known from European specimens, there can be no doubt as to their general form. On account of the presence of bony protuberances on the skull of the species figured, as well as from certain other peculiarities, such as the soldering together of the bones of the pelvis and metatarsus, Prof. Marsh regards the American form as generically distinct from the European *Megalosaurus*, and has accordingly suggested for it the name of *Ceratosaurus*. We are persuaded, however, that Prof. Cope is right in regarding the two as generically inseparable.

Passing on to the third or bird-footed (Ornithopodous) group of these reptiles, we come to some of the most specialised forms, none of which attain, however, the stupendous dimensions reached by some of the first group. The more typical representatives of this third assemblage are characterised, it need

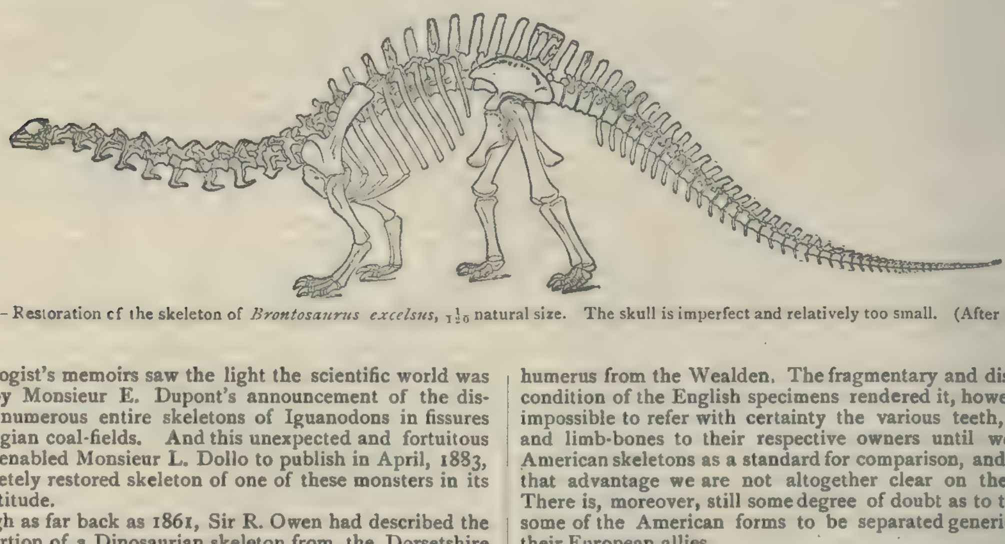

FIG. 1.—Restoration of the skeleton of *Brontosaurus excelsus*, $\frac{1}{150}$ natural size. The skull is imperfect and relatively too small. (After Marsh.)

[1] For these bones, see Fig. 3.

scarcely be said, by the generally bird-like arrangement of the pelvis, in which the front part of the ilium is much produced forwards, while the pubis has its main shaft (when present) directed backwards alongside of the ischium in a bird-like fashion (Fig. 3), and also giving off an anterior process which must not be confounded with the main shaft of the pubis of the Brontosaur (Fig. 1). The bird-footed Dinosaurs are subdivided into the armoured and the typical sections, of which the former has but lately been fully made known to us.

As our first example of the former, we take the skeleton of the Jurassic *Hypsirophus* represented in Fig. 3. The existence of this type of Dinosaur was first revealed by the discovery in 1875 of a considerable portion of a skeleton (now in the British Museum) in the Kimeridge clay of Swindon, which was described by Sir R. Owen during the same and following years under the name of *Omosaurus*;—a term which unfortunately proved to be a preoccupied one. This skeleton comprised many of a most marvellous monster. The Professor tells us that this restoration is based on a specimen which "had the skull, skeleton and dermal armour together when entombed, and almost in the position they were when the animal died. . . . In this restoration the animal is represented as walking, and the position is adapted to that motion. The head and neck, the massive fore-limbs, and, in fact, the whole skeleton indicate slow locomotion on all four feet. The longer hind limbs and the powerful tail show, however, that the animal could thus support itself as on a tripod, and this position must have been easily assumed in consequence of the massive hind-quarters. . . . . The neural spines of the vertebræ have their summits expanded to aid in supporting the massive dermal armour above them. The limb-bones are solid, and this is true of every other part of the skeleton. The feet were short and massive, and the terminal phalanges of the functional toes were covered by strong hoofs. There were five well-developed digits in the fore foot,

Fig. 2.—Restoration of a skeleton of a Carnivorous Dinosaur, $\frac{1}{30}$ natural size. (After Marsh.)

of the vertebræ and limb-bones together with some long spines similar to those represented at the end of the tail in Fig. 3. The skull is, however, missing, and there are no traces of the huge plates of bone shown in the restoration. If, however, we imagine the body of the reptile to which this skeleton pertained to have been drifting in the water sufficiently long to have lost its head by the action of decomposition, there is nothing more probable than that the row of plates along the back should have likewise disappeared. From 1877 onwards Prof. Marsh has been gradually completing our knowledge of allied reptiles from the upper Jurassic of Colorado and Wyoming, to which he applied the name *Stegosaurus*, but which appear to have been previously described by Prof. Cope under the title of *Hypsirophus*. First we had descriptions of some of the vertebræ and limb-bones, with isolated specimens of the plates and spines of the armour; then we had the head; and finally we are favoured with the restoration shown in the figure, which is certainly that and only three in the hind foot, the first toe being rudimentary, and the fifth entirely wanting."

"In life the animal was protected by a powerful dermal armour, which served both for defence and offence. The throat was covered by a thick skin, in which was embedded a large number of rounded ossicles, as shown in the figure. The gular portion represented was found beneath the skull, so that its position in life may be regarded as definitely settled. The series of vertical plates extended above the neck, along the back, and over two-thirds of the tail is a most remarkable feature, which could not have been anticipated, and would hardly have been credited had not the plates themselves been found in position. The four pairs of massive spines characteristic of the present species, which were situated above the lower third of the tail, are apparently the only part of this peculiar armour used for offence. In addition to the portions of armour above mentioned, there was a pair of small plates just behind the skull, which served to protect this part of the neck."

"All these plates and spines, massive and powerful as they now are, were in life protected by a thick horny covering, which must have greatly increased their size and weight. This covering is clearly indicated by the vascular grooves and impressions

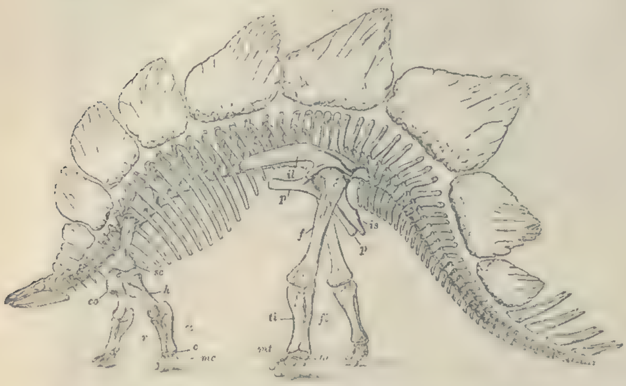

FIG. 3.—Restoration of the skeleton of *Hypsirophus ungulatus*, $\frac{1}{60}$ natural size. *sc.*, scapula; *co.*, coracoid; *h.*, humerus; *r.*, radius; *u.*, ulna; *c.*, carpus; *mc.*, metacarpus; *il.*, ilium; *p.*, pubis; *is.*, ischium; *fe.*, femur; *t.*, tibia; *fi.*, fibula; *ta.*, tarsus; *mt.*, metatarsus. (After Marsh.)

which mark the surface of both plates and spines, except their bases, which were evidently implanted in the thick skin."

To this graphic description of one of the most extraordinary creatures that lived in a world of monsters, it may be added that the remarkably tall neural arches of the dorsal vertebræ and the concomitant elevation of the proximal ends of the ribs nearly to the level of the summits of their neural spines appear to be for the purpose of aiding in the support of the enormous weight of the armour of the back.

Since we have already given more than one notice in NATURE of various portions of the horned armoured Dinosaurs of the Cretaceous of the United States, as represented by *Agathaumas* (= *Ceratops* and *Triceratops*), our notice of Prof. Marsh's recent restoration of this creature (Fig. 4) will be but brief. That these reptiles were nearly related to the Armoured Dinosaurs is undoubted; they attained, however, greater specialisation in the skull, which was of enormous size and armed with bony horn-cores, arranged as a pair above the eyes and a single one over the nose. The enormous size of the head and the proportionately large fore limbs indicate that these animals were always in the habit of walking on all fours; and, as we have previously suggested, the loss of the posterior shaft of the pubis, so well shown in the figure, is probably due to a reversion to these quadrupedal habits.

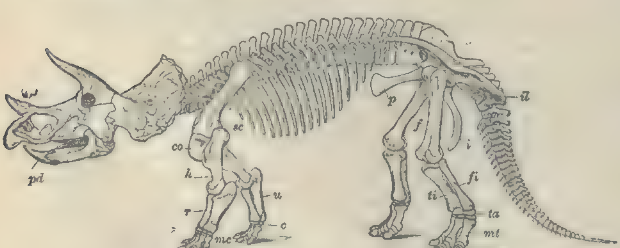

FIG. 4.—Restoration of the skeleton of *Agathaumas prorsus*, $\frac{1}{60}$ natural size. Letters as in Fig. 2. (After Marsh.)

In regard to this restoration Prof. Marsh remarks that "the skull is, of course, without its strong horny covering on the beak, hon-cores and posterior crest, and hence appears much smaller than in life. The neck seems short, but the first six cervical vertebræ are entirely concealed by the crest of the skull, which in its complete armature would extend over one or two vertebræ more. . . . . No attempt is made in this restoration to represent the dermal armour of the body, although in life the latter was more or less protected. Various spines, bosses, and plates, indicating such dermal armour, have been found with remains of this group, but the exact position of these specimens can at present be only a matter of conjecture. . . . . The size in life would be about twenty-five feet in length and ten feet in height."

The extraordinary contrast between the skeletons of *Agathaumas* and *Brontosaurus* will be sufficiently apparent from a comparison of the respective figures.

The typical section of the bird-footed Dinosaurs, as represented by the Iguanodons (Fig. 5) is now so well known that but few remarks are necessary. They differ from the armoured forms in their perfect adaptation to a bi-pedal mode of progression, their digitigrade feet, hollow limb-bones, and absence of armour; the Iguanodons being further distinguished by the curious modification of the thumb into a stout conical spine. Those who have visited of late years the Brussels Museum will not fail to retain a vivid impression of the imposing show made by two mounted skeletons of these enormous reptiles displayed in a case in the court-yard of the museum. According, however to a striking picture which appeared a couple of years ago in the *Graphic*, these two skeletons have now been removed to within a special gallery in the Museum, where, together with three others, they must excite the admiration and wonder of all who have the good fortune to behold them. With such a lavish display of their own, it is, perhaps, scarcely too much to hope that the authorities of the Royal Brussels Museum may before long see their way to enriching our own National Collection

either with an original specimen, or at least with a plaster reproduction of one of the already mounted Iguanodon skeletons.

Although there is no lack of work remaining to be done among the Dinosaurs, yet when we reflect that practically our whole definite knowledge of the group dates from within the last twenty years, and that all the five restorations at which we have glanced have been made within the last ten, we cannot but fail to be gratified at the enormous progress that has been made by this branch of palæontology within that comparatively short period. If this progress cannot be justly entitled to be termed one advancing by "leaps and bounds," yet we think that it may, on the whole, be truly described as "slow and sure."

R. LYDEKKER.

THE INTERNATIONAL MARITIME CONGRESS.

DURING nearly the whole of last week a most important congress was being held in London at the Institution of Civil Engineers. This was the International Maritime Congress, an institution founded in Paris in 1889, when no less than twenty-two papers on various maritime subjects were read and discussed, and visits were made to some of the most important seaports on the north and west coasts of France. The international commission, which constitutes the executive, determined that the second meeting of the congress should be held this year in London, and as a result the first sitting took place on July 18, when the opening proceedings were got through in the morning by the delivery of various complimentary addresses, whilst in the afternoon the more serious business of the congress commenced.

The proceedings were divided into four sections, as follows :—

Section I. Harbours, Breakwaters, &c.
,, II. Docks and their Equipment.
,, III. Shipbuilding and Marine Engineering.
,, IV. Lighthouses, Fog-signals, &c.

There were in all over forty papers set down for reading and discussion, and all but a few were so disposed of, only one or two being taken as read. Such a feat speaks highly of the industry of the various sections, and it will be understood that in this general notice we can do little more than give a list of the various papers read. Lord Brassey was president of the congress, and Mr. James Forrest, honorary secretary. Mr. C. F. Findlay was secretary. The headquarters were 25, Great George-street, Westminster.

Section I. met in the theatre of the Institution of Civil Engineers at 2 p.m., on Tuesday, July 18. It should be stated that arrangements had been made for different chairmen to officiate at the various meetings. Mr. L. F. Vernon-Harcourt was the moving spirit in this section, and naturally presided at the meetings although he did not occupy the chair.

The first business was the reading of two papers, one on "The Breakwaters and Harbours of Middlegrunden," by Capt. P. Hansen ; and a second on "The Harbour and Breakwater of Copenhagen," by H. C. V. Möller. These papers were taken together, but the meeting voted that the discussion should be deferred to the next day. A paper on "Recent Breakwaters and Sea Defences in Italy," by Chev. L. Luiggi, was next read ; and a fourth paper on "The Construction of Breakwaters," by Baron Quinette de Rochemont, brought the proceedings of the first day in this section to a close. All these papers were of a special and strictly professional character. It is to be regretted that the order in which they were originally set down was not followed, and Baron de Rochemont's contribution was not taken first. The whole of them might well have been then discussed together.

The second meeting of Section I. was held on the afternoon of the following day, when the proceedings were opened by Mr. A. G. Lyster (the Assistant Engineer of the Mersey Dock and Harbour Board) reading a paper on "Dredging the Mersey Bar." This perhaps was the most important paper of the section, inasmuch as it dealt with a practical example of what is being done to meet the most pressing maritime necessity of the day. In our last issue we pointed out that the naval architect and marine engineer had progressed so far that they had completely outstripped the harbour engineer. Advance in ship construction is really barred by the want of depth of water over dock-sills and at the mouths of ports. This is not only apparent in cross-channel service with small swift packet boats, but also with our great ocean liners. Every increase in size in steamships appears to be attended by success, but limits of draught seem now to stop progress in this direction. A paper by M. Feret on mortar in sea works was also read at this sitting ; a paper by MM. Cimino and Verdinois on rock-dredging at Palermo being taken as read.

The next sitting of Section I. was on the following Thursday afternoon, when three papers were set down for reading. The first taken was by M. P. Demey on ports on sandy coasts ; the second, by M. V. E. de Timonoff, a Russian Professor, having a similar title. The latter contribution was an interesting communication of a general nature, in which the various points involved in the consideration of the subject in regard to tideless seas were considered at large. In the discussion an interesting point was raised by an English engineer, Mr. Wheeler, as to the movement of beach. The matter was perhaps somewhat outside the legitimate scope of the discussion, as Mr. Wheeler attributed the movement of beach to the tidal movement, whilst M. de Timonoff dealt only with tideless seas. Mr. Wheeler said that the travel of beach is always in the direction of the flood—a theory which does not support the author's line of argument ; but it must again be said the action of tide was eliminated from the author's reasoning. A paper by Mr. C. Spadon on the Lido entrance to the port of Venice was taken as read.

The last sitting of Section I. was held on Friday afternoon. Two papers were on the list, one by Mr. A. E. Carey on "La Guaira Harbour Works, Venezuela," and a second, "Harbours and Ferry Systems of Denmark," by the same author.

In Section II. the first meeting was held on Wednesday morning, when the following papers were down for discussion :—"The Docks of Bordeaux," by H. Crahay de Franchemont ; "The Equipment and Working of Ports," by A. Guerard ; "The New Docks of Antwerp," by G. A. Rogers ; and "Hydraulic Installation at the Port of Genoa," by L. Luiggi and E. Borgatti. The next sitting was on the following day, when three other papers were read, viz. :—"The Port of Calais," by A. Charguérand ; "The Port of Dunkirk," by Paul Joly ; and "Lengthening of Leghorn Dry Dock," by J. Inglese. The last day of the meeting was devoted by this section to the reading of papers descriptive of the London Docks, and of the Havre and Alexandra Docks.

In the Shipbuilding Section, Section III., the papers were mostly of a moderate degree of excellence. Mr. A. E. Seaton, of Hull, opened with a good historical paper on "Cross Channel Steamers," which led to an interesting discussion. It was followed by a paper by Prof. Biles, on "Ocean Passenger Steamers." The subject has been so often dealt with, that it is difficult to say anything new upon it. On the following day, Thursday, July 20, Sir Thomas Sutherland, the chairman of the P. and O. Company, gave a general address, after which a paper by Mr. A. Blechynden, on the "Sand-pump Dredger for the Mersey Bar," the vessel already referred to, was read. This is a hopper dredger, and, we believe, the largest in existence, the capacity being no less than 3000 tons. A paper by Mr. Flannery on "The Transport of Oil in Bulk" followed. The subject is one which has been largely dealt with lately, and the author necessarily trod again a good deal of the ground occupied by Mr. Martell at Cardiff the week previously. On Friday, the last day of the meeting, a paper by Mr. C. E. Stromeyer, on "Marine Boiler Construction," was read. The scope was general, and were it not known that the author, from his position at Lloyd's, must be fairly in touch with recent practice, one might almost fancy that he had ceased to study his subject four or five years ago. The most original, and perhaps the most suitable paper to the occasion was that last taken. It was a contribution by Mr. A. Denny, of Dumbarton, entitled "Shipowners and Shipbuilders in their Technical Relationships." The subject is one that may be considered with advantage by both sides.

In the business of this section Dr. W. H. White, the Assistant-Controller of the Navy and Director of Naval Construction, took the leading part, assisted by Mr. G. Holmes, who, as Secretary to the Institution of Naval Architects, was well qualified to conduct the detail business of the section.

Section IV., that devoted to lighthouses, &c., had an attractive programme, but the proceedings were, in some cases, rather disappointing. Our space will allow us to give no more than a list of the papers set down for reading. They were as follows :—"On Compressed-air Fog Signals," by C. Ribière ; "Ship Signal Lights," by J. Kenward. These were taken on the first day, Tuesday, July 18th. A discussion was brought on by arrangement upon "Communication between Lightships and the Shore." The result was disappointing on the whole. The next day a good paper on "Feux-Éclairs, and the Physiological Perception of Instantaneous Flashes" was contributed by M. A. Blondel. M. Bourdelles also gave a paper on "Methods and Formulæ for Calculating the Luminous Power of Lighthouse Apparatus." The following day an interesting and practical paper on "The Illumination of Estuaries and Rivers" was contributed by Mr. W. T. Douglass. Two other papers were on the list for this day, the first on "Harbour Lights, Buoys, and Beacons in Italy," by D. Lo Gatto, and another on "Researches as to Continuous and Alternate Electrical Currents for Lighthouse Purposes," by A. Blondel. The last day of the meeting had three papers down for reading, viz. : "On Recent Improvements in Lighthouses," by D. A. Stevenson ; "Efficiency of Recent Gigantic Lighthouse Apparatus compared with Electric Light," by D. Lo Gatto ; and "Lighting and Light Dues in the Red Sea," by Commander G. Hodgkinson, R.N.

In connection with the Congress there were numerous dinners and other festivities, at which the foreign members were the lions of the occasion; indeed, international courtesy reigned throughout the proceedings. This was carried so far in one section that hardly anything but French was spoken, those who wished to take part in the discussions receiving but little encouragement from the chair unless they addressed the meeting in the French tongue—or, rather, in French words. This was satisfactory to the majority, so far as the remarks of foreign members were concerned; but when the language was exotic in its character to follow was sometimes laborious. This week a series of excursions are being made to some of the chief ports of the United Kingdom.

THE LUMINIFEROUS ETHER.

AT the anniversary meeting of the Victoria Institute on June 29, Sir G. G. Stokes delivered his presidential address. After a few introductory remarks on the functions of the Institute, he said:—"I intend to bring before you to-night a subject which the study of light has caused me to think a good deal about: I refer to the nature and properties of the so-called luminiferous ether. This subject is, in one respect, specially fascinating, scientifically considered. It lies, we may say, in an especial manner on the borderland between what is known and what is unknown. In the study of it it is quite conceivable that great discoveries may be made, and, in fact, great discoveries have already been made, and I may say even quite recently, and we do not at present know how much additional light on the system of Nature may be in store for the men of Science; possibly even in the near future, possibly not until many generations have passed away. I will assume, as what is familiarly known to you all, and what is well established by methods into which I will not enter, that the heavenly bodies are at an immense distance from our earth. More especially is this the case with the fixed stars. Their distance is so enormous that even when we take as a base line, so to speak, the diameter of the earth's orbit, which we know to be about 184 millions of miles, the apparent displacement of the stars due to parallax is so minute as almost to elude our investigation. Nevertheless that distance is more or less accurately determined in the case of a few of the fixed stars. But the vast majority, as we have every reason to believe, are at such an enormous distance that even this method fails with them."

"To give a conception of the immense distance of the fixed stars, I will assume as known that light travels at the rate of about 186,000 miles in one second, a rate which would carry it nearly eight times round and round the earth in that time; and yet if we take the star which, so far as we know, is our nearest neighbour, it would take three or four years for light from that star to reach the earth. Now as we see the fixed stars there must be some link of connection between us and them in order that we should be able to perceive them. Probably all of you know that two theories have been put forward as to the nature of light, as to the nature accordingly of that connection of which I have spoken. According to one idea, light is a substance darted forth from the luminous body with an amazing velocity; according to the other, it consists in a change of state taking place, propagated through a medium, as it is called, intervening between the body from which the light proceeds and the eye of the observer. For a considerable time the first of these theories was that chiefly adopted by scientific men. It was that, as you know, which Newton himself adopted; and probably the prestige of his name had much to do with the favourable reception which for a long time it received. But more recent researches have so completely established the truth of the other view, and refuted the old doctrine of emissions, that it is now universally held by scientific men that light consists in an undulatory movement propagated in a medium existing in all the space through which light is capable of passing."

"This necessity for filling all space, or at least, such an inconceivably great extent of space, with a medium, the office of which, so far as was known in the first instance, was simply that of propagating light, was an obstacle for a time to the reception by the minds of some of the theory of undulations. Men had been in the habit of regarding the inter-planetary and interstellar space as a vacuum, and it seemed too great an assumption to fill all this supposed vacuous space with some kind of medium for the sole purpose of transmitting light. Notwithstanding, even long ago strong opinions were entertained to the effect that there must be something intervening between the different heavenly bodies. In a letter to Bentley, Newton expresses himself in very strong language to this effect: 'That gravity should be innate, inherent and essential to matter, so that one body may act upon another at a distance through a *vacuum*, without the mediation of anything else, by and through which their action and force may be conveyed from one to another, is to me so great an absurdity that I believe that no man who has in philosophical matters a competent faculty of thinking, can ever fall into it. Gravity must be caused by an agent acting constantly according to certain fixed laws; but whether this agent be material or immaterial, I have left to the consideration of my readers.'"

"What the nature of the connection between the earth and the sun, for example, may be whereby the sun is able to attract the earth and thereby keep it in its orbit—in other words, what the cause of gravitation may be—we do not know; for anything we know to the contrary, it may be connected with this intermediate medium or luminiferous ether. There are other offices, we believe, which this luminiferous ether fulfils, to which I shall have occasion to allude presently."

"In connection with the necessity for filling such vast regions of space with this medium, a curious question naturally presents itself. We cannot conceive of space as other than infinite, but we habitually think of matter as occupying here or there limited portions of space, as, for example, the different heavenly bodies. The intervening space we commonly think of as a vacuum, and it is only the phenomena of light that led us in the first instance to think of it as filled with some kind of material. The question naturally presents itself to the mind—is this ether absolutely infinite like space? This is a question to which science can give no answer. Though we cannot help thinking of space as infinite, yet when we turn our thoughts to some material existing in space perhaps we more readily think of it as finite than infinite. But if the ether, however vast the portion of space over which it extends, be really limited, we can hardly fail to speculate what there may be outside its limits. Space there might be wholly vacuous, or possibly outside altogether this vast system of stars and ether there may be another system subject to the same laws, or subject to different laws, as the case may be, equally vast in extent; and if there be, then so far as we can gather from such phenomena as are open to our investigation, there can be no communication between that vast portion of space in part of which we live and an ideal system altogether outside the ether of which we have been speaking."

"But the properties of the ether are no less remarkable than its vast or even possibly limitless extent. Matter of which our senses give us any cognisance is heavy, that is to say, it gravitates towards other matter which agrees with it in so far as being accessible to our senses. The question presents itself to the mind, does the ether gravitate towards what we call ponderable matter? This is a question to which we are not able to give any positive scientific answer. If the ether be in some way or other connected with the cause of gravitation, it would seem more likely that it itself does not gravitate towards ponderable matter."

"Again, we have very strong reason for believing that ponderable matter consists of ultimate molecules. First, that supposition accords in the simplest way with the laws of crystallography. Chemical laws afford still stronger confirmation of the hypothesis, through the atomic theory of Dalton, now universally accepted. Comparatively recently, the deduction of the fundamental property of gases from the kinetic theory, as it is called, affords strong additional confirmation of that view of the constitution of matter. Still more recently, the explanation which has been afforded by that theory of that most remarkable instrument the radiometer of Crookes has lent further confirmation in the same direction. None of these evidences apply to the ether, and accordingly we are left in doubt whether it too consists of ultimate molecules, or whether on the other hand it is continuous, as we cannot help conceiving space to be."

"The undulatory theory of light was greatly promoted in the first instance by the known phenomena of sound, and the explanation which they received from the hydrodynamical theory. Accordingly, since sound, as we know, consists of an undulatory movement propagated through the air (or it may be through other media), and depending upon condensation and rarefaction, it was supposed naturally that light was propagated in a similar manner, by virtue of the forces brought into play by the condensation and rarefraction of the ether. But there is one whole class of phenomena which have actually no counterpart in those cf sound; I refer to polarisation and double refraction."

"The evidence for the truth of the theory of undulations as regards the phenomena of common light depends in great measure upon the fact of interference and the explanation which the theory gives of the complicated phenomena of diffraction. But in studying the interference of polarised light, additional phenomena presented themselves which ultimately pointed out that the vibrations with which we are concerned in the case of the ether differ altogether in their character from those which belong to sound. The phenomena of the interference of polarised light prove incontestably that there exists in light an element of some kind having relation to directions transverse to that of propagation, and admitting of composition and resolution in a plane perpendicular to the direction of transmission according to the very same laws as those of the composition and resolution of forces, or velocities, or displacements in such a plane. This requires us to attribute to the ether a constitution altogether different from that of air. It points out the existence of a sort of elasticity whereby the ether tends to check the gliding of one layer over another. Have we no example of such a force in the case of ponderable matter? We have. We know that an elastic solid, which for simplicity I will suppose to be uncrystalline, and alike in all directions, has two kinds of elasticity, by one of which it, like air, tends to resist compression and rarefraction; while by the other it tends to resist a continuous gliding of one portion over another, and to restore itself to its primitive state if such a gliding has taken place. There is no direct relation between the magnitude of these two kinds of elasticity, and in the case of an elastic solid such as jelly the resistance to compression is enormously great compared to the resistance to a gliding displacement."

"If we assume that in the ether there is really an elasticity tending to restore it to its primitive condition when one layer tends to glide over another, an elasticity which it appears to be absolutely necessary to admit in order to account for the observed laws of interference of polarised light, the question arises, can we thereby explain double refraction?"

"The earliest attempts to explain it in accordance with the theory of transverse vibrations were made by attributing to the ether a molecular constitution more or less analogous to that which we believe to exist in ponderable matter. Following out speculations founded upon that view, the celebrated Fresnel was led to the discovery of the actual laws of double refraction; the theory, however, which he gave was by no means complete, inasmuch as the results were not rigorously deduced from the premises. Cauchy and Neumann, independently and about simultaneously, took up Fresnel's view of the constitution of the ether and applied it to explain the laws of double refraction. In their theory the conclusions arrived at were rigorously derived from the premises; but the results did not altogether agree with observation; that is to say, although they could by the adoption of certain suppositions be forced into a near accordance with the observed laws of double refraction, yet they pointed out the necessity of the existence of other phenomena which were belied by observation. Our own countryman Green was the first to deduce Fresnel's laws from a rigorous dynamical theory, although nearly simultaneously MacCullagh arrived at a theory in some respects similar, though on the whole I think less satisfactory."

"Still all these theories followed pretty closely the analogy of ponderable matter; and at least in the first three mentioned the ether was even imagined to consist of discrete molecules, acting on one another, like the bodies of the solar system regarded as points, by forces in the direction of the joining line, and varying as some function of the distance. I have already quoted the very strong language in which Newton rejected the idea of the heavenly bodies acting on one another across intervening spaces which were absolutely void. But the conception has nothing to do with the magnitude of the intervening spaces; and the conception of action at a distance across an intervening space which is absolutely void, is not a bit easier when the space in question is merely that separating two adjacent molecules, when the ether is thought of as consisting of discrete molecules, than it is when the space is that separating two bodies of the solar system, though in this latter case it may amount to many millions of miles. If the ether be in some unknown manner the link of connection whereby two heavenly bodies are enabled to exert on one another the attraction of gravitation, then according to the hypothetical constitution of the ether that we have been considering, we seem compelled to invent an ether of the second order, so to speak, to form a link of connection between two separate molecules of the luminiferous ether. But since the nature of the ether is so very different as it must be from that of ponderable matter, it may be that the true theory must proceed upon lines in which our previous conceptions derived from the study of ponderable matter are in great measure departed from."

"If we think of the ether as a sort of gigantic jelly, we can hardly imagine but that it would more or less resist the passage of the heavenly bodies—the planets for instance—through it. Yet there appears to be no certain indication of any such resistance. It has been observed indeed in the case of Encke's comet, that at successive revolutions the comet returned to its perihelion a little before the calculated time. This would be accounted for by the supposition that it experienced a certain amount of resistance from the ether. Although at first sight we might be disposed to say that such a resistance would retard perihelion passage, yet the fact that it would accelerate it becomes easily intelligible, if we consider that the resistance experienced would tend to check its motion, and so prevent it from getting away so far from the sun at aphelion, and would consequently bring it more nearly into the condition of a planet circulating round the sun in a smaller orbit."

"Many years ago I asked the highest authority in this country on physical astronomy, the late Prof. Adams, what he thought of the evidence afforded by Encke's comet for the existence of a retarding force, such as might arise from the ether. He said to me that he thought we did not know enough as to whether there might not possibly be a planet or planets within the orbit of Mercury which would account for it in a different way. But quite independently of such a supposition it is worthy of note that the remarkable phenomena presented by the tails of comets render it by no means unlikely that even without the presence of a resisting medium, and without the disturbing force arising from the attraction of an unknown planet situated so near to the sun as not to have been seen hitherto, the motion of the head of a comet might not be quite the same as that of a simple body representing the nucleus, and being subject to the gravitation of the sun and planets and nothing else. It appears that the tails consist of some kind of matter driven from the comet with an enormous velocity by a sort of repulsion emanating from the sun. If the nucleus loses in this manner at each perihelion passage an exceedingly small portion of its mass, which is repelled from the sun, it is possible that the residue may experience an attraction towards the sun over and above that due to gravitation, and that possibly this may be the cause of the observed acceleration in the time of passing perihelion even though there be no resistance on the part of the ether. So that the question of resistance or no resistance must be left an open one."

"The supposition that the ether would resist in this manner a body moving through it is derived from what we observe in the case of solids moving through fluids, liquid or gaseous, as the case may be. In ordinary cases of resistance, the main representative of the work apparently lost in propelling the solid is in the first instance the molecular kinetic energy of the trail of eddies in the wake. The formation of these eddies is, however, an indirect effect of the internal friction, or if we prefer the term viscosity, of the fluid. Now the viscosity of gases has been explained on the kinetic theory of gases, and in the case of a liquid we cannot well doubt that it is connected with the constitution of the substance as not being absolutely continuous but molecular. But if the ether be either non-molecular, or molecular in some totally different sense from ponderable matter, we cannot with safety infer that the motion of a solid through it necessarily implies resistance."

"The luminiferous ether touches on another mysterious agent, the nature of which is unknown, although its laws are in many respects known, and it is applied to the every-day wants of life, and its applications are even regulated by Acts of Parliament; I allude to electricity. I said that the nature of electricity is unknown. More than forty years ago I was sitting at dinner beside the illustrious Faraday, and I said to him that I thought a great step would have been made if we could say of electricity something analogous to what we say of light, when we affirm that light consists of undulations; and he said to me that he thought we were a long way off that at present. But, as I said, relations have recently been discovered between light and electricity which lead us to believe that the latter is most closely connected with the luminiferous ether."

"Clerk-Maxwell showed that the ratio of two electrical constants which are capable of being determined by laboratory experiments, and which are of such a nature that that ratio expresses a velocity, agrees with remarkable accuracy with the known velocity of light. This formed the starting-point of the electro-magnetic theory of light which is so closely associated with the name of Maxwell."

"According to this idea, light may be looked on as the propagation of an electro-magnetic disturbance, whatever the appropriate idea of such a thing may actually be. The theory has quite recently received remarkable confirmation by the investigations of Hertz, who has shown that what are incontestably electro-magnetic disturbances, and are investigated by purely electrical means, exhibit some of the fundamental phenomena of light, such, for example, as interference and polarisation. It appears that these electro-magnetic waves are strictly of a similar nature to the waves of light, though there is an enormous difference in the scale of wave-lengths, which in the case of light range about the $\frac{1}{50000}$th part of an inch, while the electro-magnetic waves which have been investigated by purely electrical methods range from a few inches to many yards."

"I have ventured to bring this interesting subject before you in the course of the address which I have just delivered. I have not attempted to lay before you the evidence on which scientific men rely for the truth of the conclusions which I have mentioned as well established. That would have required, not merely an evening address, but a whole course of lectures. Neither have I made any allusion to possible bearings of the scientific conclusions on questions relating to religious beliefs. Anything of that kind I leave to your own minds; my object has been simply to present to you very briefly the conclusions of science in that limited branch which I have selected, distinguishing as impartially as I could what is well established from what is debatable or even merely conjectural."

THE NATURE OF DEPOLARISERS.[1]

WHEN an electric current is passed between plates of platinum through a solution of sulphuric acid, the hydrogen and oxygen are partly retained at the surfaces—and apparently also within the plates—and under these conditions are capable of interacting, as in the well-known Grove gas battery: so that in so far as the "gases" thus circumstanced are concerned the change may be expressed by a reversible equation. This reversal constitutes the well-known phenomenon termed polarisation by physicists.

Reversal owing to the retention of hydrogen in circuit is promoted to different extents by different metals—hence apparently the varying electromotive forces of single fluid cells containing different negative plates; and when the pressure is sufficient to retain the whole of the hydrogen at the plate, it becomes total—hence it is, for example, that zinc does not dissolve in sulphuric acid under great pressure.

Various substances known generally as depolarisers are used to prevent the accumulation of products of electrolysis and the consequent reversal of the action—such as copper sulphate in the case of the Daniell cell and "nitric acid" in the case of the Grove and Bunsen cells; but whereas the action of copper sulphate is easy to understand, that of "nitric acid" offers many difficulties. As the heat of dissolution of copper in dilute sulphuric acid is a negative value (about 12,000 units), the displacement of copper by hydrogen—*i.e.* the heat of dissolution of hydrogen in copper sulphate—is a positive value, so that not only does the presence of the copper sulphate prevent the accumulation of hydrogen, but in removing hydrogen it also serves to increase the electromotive force of the cell from about 37/46ths to about 50/46ths of a volt. The principle underlying this is extensible even to cases in which one part of the cumulative effect of the cycle of change is a negative value. Thus, although copper has a negative heat of dissolution, it will readily dissolve in dilute sulphuric acid if it be used in place of zinc in a Grove cell, the negative heat of dissolution of copper being more than compensated for by the positive heat of dissolution of hydrogen in "nitric acid"; and it is well known that copper dissolves in many weak acids in presence of oxygen. It is easy to understand how oxygen acts in such cases, but the facts show that the effect produced by "nitric acid" is not so readily interpreted, and their consideration raises important questions of general application.

Russell has shown that when "nitric acid" is freed from nitrous compounds it does not dissolve silver, but that action sets in when a trace of nitric oxide is introduced, and continues with increasing rapidity as the quantity of the nitrous compound—a necessary product of the action—increases; Veley's later experiments have shown that the same is true of copper, without, however, affording any further explanation of the phenomena. Although it is not to be expected that such metals would dissolve in nitric acid even when coupled with a relatively electronegative conductor, as they have negative heats of dissolution, yet if the acid also acted as depolariser a cycle might be formed in which sufficient energy would be developed to condition change: it therefore follows that in such cases *nitric acid* does not act as the depolariser in accordance with the equation: $2Ag + 2NO_3H + ONO_2H = 2AgNO_3 + H_2O + NO_2H$, and that in point of fact the nitrous compound is the depolariser, although the nitric acid is the actual solvent of the metal, the hydrogen of the acid being virtually directed displaced by the metal with the assistance, however, of the current energy derived from its own oxidation by the nitrous compound.

But what interpretation is to be given of the behaviour of more active metals, such as zinc, magnesium, &c., which have positive heats of dissolution, and therefore are capable of dissolving in the pure dilute acid if coupled with a relatively negative conductor; does nitric acid in their case directly act as a depolariser? If it be capable of thus acting, such metals even when uncoupled should dissolve in the pure diluted acid. It is noteworthy that when such metals are dissolved in nitric acid hydrogen is sometimes evolved. It has been suggested that this hydrogen is derived from the interaction of the metal and water, but I cannot now regard this as a probable explanation; its production serves rather to suggest a deficiency of the depolarising agent, which cannot well occur if nitric acid be the depolariser. Indeed, if nitric acid be regarded as directly active, it is remarkable that in presence of the large excess of the acid which is always present any hydrogen should escape; and also that the reduction should extend so far as it often does, and not extend merely to the formation of nitrous acid. If, however, the acid be incapable of directly acting as a depolariser, and a nitrous compound be the initially active depolarising agent, it is no longer surprising that owing to the nitrous compound suffering further reduction it should be deficient in parts of the circuit, and that consequently hydrogen should escape. Why the reduction should extend so much further when metals having positive heats of dissolution are used, however, still requires elucidation.

In the case of sulphuric acid, whatever metal be dissolved in the *diluted* acid, no reduction takes place; and it is only when the concentrated and more or less heated acid is used that sulphurous oxide and other reduction products are obtained. It appears not improbable that reduction only takes place under conditions under which the presence of sulphuric *oxide* is possible, *i.e.* that depolarisation is effected by sulphuric *oxide* and never by sulphuric *acid*, although this latter may be regarded as the actual solvent of the metal. There is at present no evidence forthcoming to show that nitric acid can dissociate into the anhydride and water, and even if such a change took place in concentrated solutions, there is no reason to assume that it can also take place in dilute solutions, and that this is the explanation of the difference between nitric and sulphuric acids. It is well known, however, that nitric acid is resolved with extreme facility into nitrogen dioxide, water and oxygen, and that it is excessively sensitive to the action of nitric oxide—a trace of nitric oxide would therefore exercise a fermentative action and condition, the formation, it may be, of nitrous acid, or—as there is no evidence compelling us to suppose that the compound represented by the formula HNO_2 exists—it may be of nitrogen dioxide. In this latter case, solutions of nitric acid would resemble concentrated sulphuric acid in containing a reducible oxide, and it may be that their depolarising action is initially exerted through such an oxide alone.

To arrive at a clear conception of the function of acids in dissolving metals, and of the nature of depolarising agents, it would therefore appear to be necessary to take into account many circumstances to which hitherto but little attention has been paid.

HENRY E. ARMSTRONG.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

IN a letter to the *Times* of July 25, Mr. J. Parker Smith, M.P., describes the action that has been taken by Wykehamists with a view of commemorating the 500th anniversary of the opening of Winchester College by some permanent memorial. It was resolved last May that any fund which might be raised should be applied, first, to the restoration of the Founder's Chantry in the Cathedral, and secondly, to establishing a group of memorial buildings for the preservation of Wykehamical antiquities and the encouragement of art, archæology, natural history, and other sciences. Mr. Smith is the Chairman of the Executive Committee formed to administer the funds, and he says that the aims of the collection of archæology and art would be to illustrate and encourage the regular course of school study, and to furnish boys with interests outside that course. As to science, the idea is that the science collections should be a development of the present collection of the Natural History Society, which is good though not large. Mr. Smith thinks that special stress would doubtless be laid on the collection of local minerals, fauna, and flora. An attempt might also be made (as has been done at Harrow) to imitate the admirably instructive series of type forms exhibited in the Museum of Natural History at South Kensington; and it would be highly desirable to connect some moderate provision for elementary biological and botanical work with the natural history museum. Contributions to the fund will be received by the hon. secretary, Mr. Percy R. T. Toynbee, 109, Gloucester Terrace, Hyde Park, W.

THE sixth annual meeting of the National Association for the Promotion of Technical and Secondary Education was held on July 24. The Duke of Devonshire, who occupied the chair, said that public funds had been so rapidly secured for purposes of technical instruction that in some cases both county councils and municipal authorities were at a loss to decide upon the best means of administering them. He thought that it might be advisable for another Royal Commission to be appointed to inquire and report upon the progress made since 1881 in our own and in Continental countries. He was glad to see that the county councils of Staffordshire, Bedfordshire, and Manchester had sent their organising secretaries to the Continent to ascertain the latest developments of technical education abroad, and hoped that their example would be followed by others. Sir Henry Roscoe presented the report of the Society, and its adoption was moved by Mr. Mundella, and supported by Sir F. S. Powell. The officers of the Society were re-elected, with the addition of Sir W. Hart-Dyke as a vice-President, and Sir A. Rollit as a member of the executive committee.

AS an outcome of the Technical Instruction Act, a scheme was promoted, and plans subsequently adopted, for the erection of technical schools at Maidstone, and the foundation stone of the new buildings has just been laid. The schools, which are commodious and well adapted for the purpose for which they will be used, have received the sanction of the Science and Art Department, and comprise, on the ground floor, science, lecture, and class rooms—the former capable of seating from sixty to eighty-four students—large lecture hall, and a library, together with physical and chemical laboratories, and a wood-carving workshop. On the first floor is the art school, with painting and modelling rooms, and a life studio. The basement is designed for an electric installation and stores. There being a large available space in the vicinity of the Maidstone Museum, the new buildings will form an adjunct, and both in the science and art departments direct communication may be had with that institution, which will thus mutually further the objects of the whole group.

THE following alterations, among others, have been introduced into the programme of techniological examinations of the City and Guilds of London Institute for the session 1893-94. 1. An examination in cabinet-making and one in metal-work as a branch of manual training have been added. 2. The syllabus in boot and shoe manufacture has been divided into two grades, and separate practical tests are added to each grade. 3. The honours examination in photography is divided into two sections—(1) pure photography and (2) photo-mechanical processes—and the practical examination will be held in connection with the honours grades only. 4. The examination in cotton weaving in the ordinary grade is divided into two sections—(1) plain weaving and (2) fancy weaving. 5. An examination preliminary to that in the ordinary grade will be held in electric lighting and in typography; and the examination in typography in the ordinary grade is divided into two sections. 6. The syllabus in silk weaving is enlarged so as to include riband weaving. 7. The syllabuses in cloth weaving, flax spinning, hosiery, goldsmiths' work, brick-work, and in other subjects have been revised.

DR. DENDY, who for the past five years has held the position of demonstrator and assistant lecturer in biology in the University of Melbourne, has been appointed lecturer in biology at the Canterbury College, in the University of New Zealand, and will enter upon his duties there in February next. At present Dr. Dendy has sole charge of the biological department during the absence of Prof. Spencer in England.

MR. STANLEY DUNKERLY, M.Sc., has been appointed assistant-lecturer in engineering at the Walker Engineering Laboratories, University College, Liverpool.

LAST year the Staffordshire Technical Education Committee sent a number of teachers to Leipzig for a course of manual training in wood-work, iron-work, &c., at Dr. Gotze's Institute. The plan is again being followed this year, not only in Stafford but by other counties that have come to recognise its usefulness.

SCIENTIFIC SERIALS.

American Journal of Science, July.—The following are among the papers appearing in this number:—Studies of the phenomena of simultaneous constrast colour; and on a photometer for measuring the intensities of lights of different colours, by Alfred M. Mayer. The photometer was constructed in such a manner that the two tints to be compared were reduced to the same by the effects of contrast. Two discs, 13cm. in diameter, and having half of their surface removed in the shape of eight equidistant sectors, were made of thin Bristol board. Between them was placed a circle of white translucent tracing paper, and the discs were clamped together with the open sectors coinciding. The compound disc was mounted on a rotator and placed opposite two silvered mirrors inclined at an angle of 150°. The plane of the disc bisected the angle formed by the mirrors, so that the surfaces of both sides could be seen simultaneously. On rotating the disc while illuminated by daylight on the one side and by lamplight on the other, the side illuminated by daylight appeared white tinted with yellow, the other appeared white tinted with blue. A compound disc of red lead, of chrome yellow, and of white cardboard was placed on the daylight side, and an ultramarine, emerald green and white disc on the lamplight side. The greenish-blue produced by the latter combination made the light blue on the lamplight side appear faintly orange-yellow by contrast, while on the other side of the ring the orange-yellow disc had diminished the orange-yellow tint of the ring to the same feeble orange-yellow as seen on the other side.—On the ammonium-lead halides, by H. L. Wells and W. R. Johnston, and on the rubidium-lead halides, and a summary of the double halides of lead, by H. L. Wells. The authors are of opinion that not one of the many complicated ammonium-lead halides described by André really exists, but that the bodies obtained by him were mixtures. They themselves succeeded in preparing five salts representing three different proportions of ammonium and lead.—A one-volt standard cell, by Henry S. Carhart. This is a calomel and zinc chloride cell adjusted to an E.M.F. of one volt by a proper concentration of the zinc chloride solution. In the bottom of the tube is pure mercury in contact with platinum wire; then follows a paste of mercurous chloride and zinc chloride held in position by a cork diaphragm; and finally an amalgamated zinc rod immersed in zinc chloride solution of density 1·391 at 15°C. The cell has a small positive temperature coefficient.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 8.—"The Influence of Exercise on the Interchange of the Respiratory Gases," by W. Marcet, M.D., F.R.S.

The following is a summary of the contents of this paper:—1st. It was shown that in three persons out of four who submitted to experiment there was a great tendency to an uniformity of figure for the oxygen *consumed* under similar physical circumstances (food, temperature, &c.), so that, if the CO_2 expired fell, the oxygen absorbed rose, and *vice versâ;* this was accounted for by assuming that an increase of CO_2 in the blood in the state of repose is produced at the expense of the O absorbed. The fourth person experimented upon exhibited no such tendency, the CO_2 expired and O absorbed rose and fell together, which was ascribed to the fact that he was still growing.

2nd. Experiments were made on the influence of exercise on respiration, which showed that if stepping exercise (stepping at the rate of sixty-eight times per minute) is taken after a period of rest, there occurs for a few minutes an accumulation of CO_2 in the blood; of course the storage of CO_2 after exercise must be controlled by the normal amount of CO_2 produced in repose, and the kind of exercise taken; this storage would in the cold winter weather, and between one and two hours after food, continue for about eighteen or twenty minutes. In my case the volume of CO_2 retained in the blood amounted to a mean of 500 c.c. while stepping sixty-eight times per minute. The CO_2 in store is next given out in the form of a wave, which is renewed after a certain lapse of time, so that there does not appear to be in respiration under exercise a fixed relation between the CO_2 expired and the CO_2 left in the blood. With practice and training this relation would probably become more and more uniform.

The storage of CO_2 in winter and after food was found to exhibit a certain relation to the excess of CO_2 expired under exercise over the CO_2 expired in repose; but eighteen or twenty minutes after exercise had been commenced this relation failed to show itself any longer.

The ratio in question was the same with two different persons; but further experiment is required to determine whether this ratio can be looked upon as general; the mean relation found is shown by the figure 0·123; therefore, so far as the present inquiry goes, by multiplying this figure 0·123 by the excess of CO_2 given out per minute under exercise over the CO_2 expired in repose during the same lapse of time, the result will show the volume of CO_2 absorbed in the blood per minute.

3rd. After the exercise adopted in this inquiry had been followed by a complete repose of ten minutes, the CO_2 expired had returned to the normal in repose, but the volume of O absorbed per minute had considerably fallen, apparently owing to the blood having charged itself with oxygen during exercise, so that the first few minutes after rest was taken, the blood was in a condition to supply oxygen for tissue-changes without taking it from the air breathed at the time. After half an hour's perfect rest following exercise the respiratory changes had returned to their normal state of repose, or nearly so, the oxygen absorbed still occasionally showing signs of being a little lower than before exercise had been taken.

June 15.—"On a Graphical Representation of the Twenty-Seven Lines on a Cubic Surface." By H. M. Taylor, Fellow of Trinity College, Cambridge. Communicated by A. R. Forsyth, F.R.S.

The converse of Pascal's well-known theorem may be stated thus: if two triangles be in perspective, their non-corresponding sides intersect in six points lying on a conic. An extension of this theorem to three dimensions may be stated thus: if two tetrahedrons be in perspective, their non-corresponding faces intersect in twelve straight lines lying on a cubic surface. This theorem may be deduced from the equation

$$xyzu = (x + a\mathrm{T})\ (y + b\mathrm{T})\ (z + c\mathrm{T})\ (u + a\mathrm{T}),$$

where $\mathrm{T} = \alpha x + \beta y + \gamma z + \delta u$; and $a, b, c, d, \alpha, \beta, \gamma, \delta$ are constants. The equations of twelve lines on the surface are evident.

This paper shows how the remaining fifteen straight lines on the surface may be obtained by means of nothing higher than quadratic equations, and determines which of these lines intersect each other.

The paper then proceeds to give a graphical method of representing all the intersections of the twenty-seven lines on a cubic surface by means of a plane diagram, which admits of many interesting transformations.

By the help of such diagrams some of the known relations of the twenty-seven lines to each other are deduced, and some theorems with respect to the lines which it is believed are new are established; for instance, the number of closed quadrilaterals, pentagons, and hexagons on the surface is determined, as well as the number of ways in which nine triple tangent planes can be drawn to pass through all the twenty-seven lines, and the number of ways in which twelve of the lines can be chosen, so that they are the intersections of two tetrahedrons in perspective.

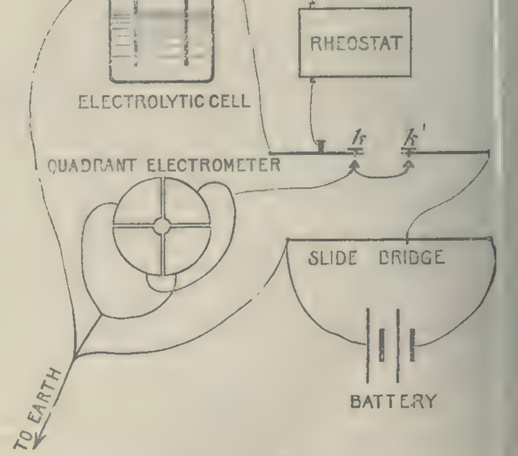
"Polarisation of Platinum Electrodes in Sulphuric Acid." By James B. Henderson, B.Sc. Communicated by Lord Kelvin, P.R.S.

This investigation was begun about the beginning of February, 1893, at the instigation of Lord Kelvin, and was conducted in the Physical Laboratory of Glasgow University. The object of the investigation was to obtain the difference of potential between two platinum electrodes immersed in a solution of sulphuric acid immediately after the stoppage of a current which had been electrolysing the solution, and to find how this difference varied with a variation in the intensity of the current or in the strength of the solution.

Former experiments by Buff and Fromme have given for the maximum polarisation with platinum wires of very small surface in the electrolysis of dilute sulphuric acid 3·5 and 4·6 volts.

Dr. Franz Richarz says of the above:—"In these experiments the polarisation is calculated from measurements of the intensity of the galvanic current during the electrolysis, tacitly assuming that the resistance of the decomposition cell is independent of the intensity of the galvanic current. The correctness of the supposition has not been proved." By employing a different method he found values for the polarisation never greater than 2·6 volts with small wire electrodes, and also got the same maximum with large platinum plates.

The electrodes in the present investigation were rectangular plates of platinum foil 7 cm. long by 5·5 cm. broad, and were immersed in the solution to a depth of 5 cm., having their planes parallel, and about 1 cm. apart. There were thus 55 sq. cm. of surface of each plate wetted. To find the polarisation one of Lord Kelvin's Quadrant Electrometers was used. The method used can be best understood from the diagram. By means of



the key k the breaking of the electrolysing current circuit and the switching of the electrodes on to the terminals of the electrometer were done simultaneously. Before switching as above, however, the needle of the electrometer was deflected by keeping the key k' down, thereby making a difference of potential between the pairs of quadrants equal to that between the slider and the earthed end of the high resistance slide bridge, and this deflection was adjusted by trial and error, so that when k was pressed no further deflection took place. To secure this, at the beginning of an experiment, the slider was placed so that when k was momentarily pressed, the deflection of the electrometer needle was increased impulsively. The amount of this impulsive deflection was noted, and the slider moved so as to increase the steady deflection nearly up to the point on the scale reached by the impulsive one, and then another trial was made. In this way, by watching the point reached by each impulsive deflection, and then increasing the steady one almost up to that point, the latter was increased until the former vanished—that is, until the potential of the quadrants was that of polarisation. The magnitude of this deflection was then noted and the polarisation calculated from it.

All the results point to the polarisation being constant with large electrodes, being independent of the strength of the solution and the intensity of the current. The results of one series of experiments are given in the accompanying table. The variations in the figures do not occur in any order, and are all such as might be expected in experimental results of this nature. Some of the greatest variations were obtained in exactly similar experiments performed at different times.

Percentage strength of solution.	Strength of current in ampères.	Time the current had been passing.	Polarisation in volts.

"On the Displacement of a Rigid Body in Space by Rotations. Preliminary Note." By J. J. Walker, F.R.S.

Having been led to study more particularly than, as far as I am aware, has hitherto been done the conditions of the arbitrary displacement of a rigid body in space by means of rotations only, the results arrived at in the case of the single pairs of axes seem to me of sufficient interest and completeness to warrant their being recorded.

A comparison of these results with those arrived at by Rodrigues in his classic memoir "Des lois géométriques qui régissent les déplacements d'un système solide dans l'espace . . . ." Liouville, vol. v. 1840, at once suggesting itself, it may be proper here to recall the substance of the latter, and show how far they fall short of the object I propose to myself. The case of displacement by successive rotations round a pair of axes is discussed in § 13 (pp. 395–396), where it is shown that (p. 390), "Tout déplacement d'un système solide peut être représenté d'une infinité de manières par la succession de deux rotations de ce système autour de deux axes fixes non convergents. Le produit des sinus de ces demi-rotations multipliés par le sinus de l'angle de ces axes et par leur plus courte distance, est égal, pour tous ces *couples* d'axes *conjugués*, au produit du sinus de la demi-rotation du système autour de l'axe *central* du déplacement, multiplié par la demi-translation absolue du système."

Then (p. 396) the converse of this theorem is affirmed, viz., that "*Tout déplacement . . . peut toujours provenir, d'une infinité de manières, de la succession de deux rotations autours de deux axes non-convergents* pourvu que *le produit. . . .*"

In this conversion of the theorem above, it is strangely overlooked that a displacement is not defined by the direction of axis, and amplitude, of the resultant rotation, together with the magnitude of the component of the corresponding translation along that direction (for in this form the proof is given, the axis being drawn through one end of the common perpendicular to the particular couple in respect of which the theorem is demonstrated), since these elements are common to an infinity of displacements.

These being premised, the laws connecting pairs of axes by successive rotations round which a given displacement of a rigid body in space may be effected are as follows:—

If the first axis is taken parallel to a given vector, ζ', there are four directions, to any one of which (ζ) its conjugate may be parallel, viz., the sides common to two quadric cones, the constants of which are functions of ζ' and the vectors defining the displacement.

One of these cones, whatever the direction of ζ', passes through the vector which is the axis of resultant rotation for the origin, or, in other words, which is parallel to the *central* axis for the given displacement. The other cone (K) passes through a vector covariant with ζ', say ζ_1.

The direction ζ' and any selected one of the four vectors ζ being taken for a pair of axes of rotation, the corresponding amplitudes are thus determined, viz. that of the second rotation is double the angle between the planes of the vectors ζ, ζ' and ζ, ζ_1. And as, ζ being fixed, ζ' lies on two cones, one of which, K′, contains a side (ζ'_1) corresponding to the side ζ_1 of K, the angle of rotation round the first axis is double that between the planes of the vectors ζ', ζ and ζ', ζ'_1. The planes of ζ, ζ_1 and ζ', ζ'_1 meet in the vector parallel to the central axis.

The directions of the axes being fixed in accordance with the above conditions, the locus of either axis is a plane, the places of the axes in which are so related that the connector of the feet of perpendiculars on them from any fixed point generates a ruled quadric surface.

As regards the *reality* of the conjugates (ζ) corresponding to an arbitrary direction (ζ') assumed for the first axis, it may suffice here to state that one real conjugate, at least, is insured by taking as ζ' any side of the quadric cone which is defined by replacing ζ in the cone K with the vector parallel to the *central* axis. The two cones, whose common sides are directions of the corresponding conjugate, then both passing through that vector, will meet in at least one other real side.

Academy of Sciences, July 17.—M. de Lacaze-Duthiers in the chair.—On the discovery of the comet b 1893, by M. F. Tisserand.—Expression of the resistance offered by each ponderable molecule to the vibratory motion of the ambiant ether, by M. J. Boussinesq.—On the generalisation of a theorem of Euler relating to polyhedra, by M. H. Poincaré.—Experiments on the resistance of air and diverse gases to the motion of bodies, by MM. L. Cailletet and E. Colardeau. The experiments previously made on the resistance of air to the motion of falling bodies, and performed at the Eiffel Tower, led to varying results according to the pressure of the atmosphere. In order to determine the influence of the pressure upon the resistance, and also that of the nature of the gas, the apparatus was enclosed in a cast-iron receiver of 300 litres capacity, into which air or other gas could be pumped up to pressures of 8 or 10 atmospheres. The apparatus consisted of a paddle-wheel set in motion by a weight suspended by a string wound upon the shaft. A double cock, with intermediate reservoir, permitted the introduction of a known quantity of shot into the cylindrical hollow of the driving weight, so as to increase the weight without affecting the pressure. A key, worked from the outside through a stuffing-box, enabled the experimenters to replace the weight as often as desired without loss of compressed gas. The downward motion of the weight became uniform as soon as the resistance of the gas equalled the driving weight. An electric contact inside the receiver connected with a bell outside indicated the rate of rotation of the paddle-wheel. The resistance opposed by any gas to the motion of a plane was found to be proportional to its surface, the square of its velocity, and the pressure and density of the gas. If two planes are placed one behind the other at a distance equal to their breadth, the total resistance is about 1·1 times that offered to a single plane. Placing two planes 0·15 m. broad 1 m. apart, the sum of their resistances did not come up to twice the resistance of each.—Observations of the new comet Rordame, made with the great equatorial of the Bordeaux Observatory, by MM. G. Rayet and L. Picart.—On a relation which exists between the formulæ of Coulomb (magnetic), Laplace, and Ampère, by M. E. H. Amagat. It is shown that W. Weber's method of arriving at the values of the constants of Ampère's formula is incorrect. M. Amagat hopes shortly to obtain some more accurate results.—On glycolysis in normal and diabetic blood, by MM. R. Lépine and Métroz. In diabetic blood the absolute loss of sugar *in vitro*, although quite perceptible, is very much less than it would be if the glycolytic energy were normal; it is, therefore, evident that the glycolytic energy must be lowered.—On the new comet *b* 1893, by M. Quénisset.—Observations of the new comet, *b* 1893, made at the Paris Observatory (west equatorial), by M. G. Bigourdan.—On studies of the discharge of vapour through orifices, by M. H. Parenty.—On the simplicity of samarium, M. Eug. Demarçay. AMSTERDAM.

Royal Academy of Sciences, June 24.—Prof. van de Sande Bakhuyzen in the chair.—Mr. Kamerlingh Onnes gives the results of some experiments made in the Leyden Laboratory (1) by Dr. Kuenen, on the surface of v. d. Waals for mixtures. One of the phases observed by Wroblewski in compressing air with CO_2, and by Prof. Dewar in compressing CS_2 with CO_2 is due to insufficient mixing. (2) By Dr. Siertsema, on the magneto-optic dispersion of oxygen. The apparatus used is like that of Kundt and Röntgen, but the polariser and analyser are Nicols', and the coil is magnetised by a dynamo of 8 h.p. The magnetic rotation of the plane of polarisation diminishes regularly as the wave-length increases.—Mr. J. A. C. Oudemans communicated some remarks concerning Sir John Herschel's second method of calculating the most probable orbit of a binary star, (Mems. of the R.A.S., vol. xviii.). The apparent orbit is here determined analytically by applying the method of least squares to the solution of the equations

$$\alpha x + \beta y + \gamma x^2 + \delta xy + \epsilon y^2 + 1 = 0,$$

where α, β, γ, δ, ϵ are the unknown quantities, x, y the coordinates given by the normal places. Sir John gave these equations equal weights, whereas the speaker proved that the weight of each equation $= p = \frac{1}{P^2 + Q^2}$, P being $= \alpha + 2\gamma x + \delta y$, and $Q = \beta + \delta x + 2\epsilon y$. In the example given by Sir John (the orbit of γ Virginis) p varies from the single to the treble. If the weight of a normal place is estimated, from other considerations (*i.e.* the power of the telescopes, the number of observations, &c.), $= p'$, the weight of the corresponding equation is to be taken $= pp'$. Mr. Franchimont asserts the possibility that glucose, being aldehyde and alcohol together, would, by the known interaction of these two functions, *i.e.* an addition, give in some circumstances derivatives of a tautomeric form, an oxide, whenever this does not exist in the free state. In such a tautomeric form (the most probable is 1·2) there is one asymmetric carbon atom more than in the aldehydic form, and he inclines to consider the two pentacetates as the stereoisomeric derivatives of this carbon atom. The two pentacetates (also the tetracetate chloride of Colley and the pentabenzoate of Skraup) have no properties of aldehyde, neither of alcohol. They cannot be compared with oxides, such as ethylenic-oxide, nor with the lactones (olides). They differ in melting-point, solubility, and optical activity. Both are dextro-rotatory, but the power of rotation of the one is very small, that of the other very great. In association with Mr. Lobry de Bruyn he could not find any difference in the chemical behaviour, so that no reason exists to admit that they are structural isomeric. With ammonia they seem to produce acetamide and the same product that is given by glucose itself, isomeric with glucosamine and isoglucosamine. The pentacetate with the higher melting-point can be transformed in that with the lower by heating with zinc-chloride, the presence of a solvent as xylene being favourable but not necessary. The above considerations on the tautomeric form of glucose can be applied on other aldols (olals) and throw new light on their peculiar behaviour in some circumstances.

A CATALOGUE OF SNAKES.

Catalogue of the Snakes in the British Museum (Natural History). Vol. I. By George Albert Boulenger. (London: 1893.)

IN the present volume Mr. Boulenger, the author of the Catalogues of Batrachia, and of the Lizards, Tortoises, Rhynchocephalians and Crocodiles, amongst the Reptilia, commences the description of the only order of living reptiles not hitherto treated by him in the octavo series of British Museum Catalogues.

The Ophidia, whether regarded as a distinct order, as they appear in the text of the catalogue, or as one of the suborders of Squamata, with the Lacertilia and Rhiptoglossa (Chameleons) forming the other sub-orders, as advocated in a foot-note, are by far the most important group of living reptiles after the lizards, and are, like the latter, of comparatively recent origin. No remains of true snakes have been recognised in deposits older than upper cretaceous.

Few groups of vertebrate animals have proved as difficult to classify correctly as snakes. The absence of limbs and the peculiarly specialised (elongate form have made species, genera, and even in some cases families resemble each other far more exactly than is usually the case. The result in this and in some similar instances has been that characters of little or no intrinsic value have long been regarded as distinctive, and that an artificial system has been adopted. Certainly in the case of the snakes there was every excuse for characters which are now known to be adaptive and of secondary value in classification, being long supposed to be of primary importance, for the principal of these characters consisted in the presence or absence of weapons by which the life of large animals, including man, could be destroyed with extraordinary rapidity. The first inquiry naturally made by any person confronted by a snake is, "Is it poisonous?" and as the question whether the animal can or cannot inflict an injury that may be, and very often is known to be, fatal, can be certainly decided by examining the structure of the teeth, it is far from surprising that that structure should long have been accepted as the criterion for dividing snakes into primary groups. It was of course recognised that vipers and rattlesnakes, which present marked external differences from such poisonous serpents as the cobra, must be kept distinct from the latter, and consequently all ophidians were until quite recently divided into three groups, (1) harmless snakes; (2) venomous colubrine snakes, and (3) viperine snakes, both the two latter, or poisonous sections, being distinguished by having a grooved or perforated tooth situated at the anterior extremity of the maxillary on each side, and supplied with a poisonous secretion from the very slightly modified salivary gland.

But it had long been known that amongst the so-called harmless colubrine snakes there were several genera such as Dipsas, Psammophis, and Homolopsis, with grooved teeth exactly similar in structure to those characteristic of poisonous forms, but situated at the posterior instead of the anterior termination of the maxillary. These snakes, the Opisthoglypha, as they are termed, were kept apart from other colubrine snakes by several herpetologists, but it is only within the last few years that their poisonous character has been distinctly ascertained. It is true that owing to the position of the grooved fangs, and also to the small quantity of poisonous secretion, the bite of these snakes is harmless to man and to the larger animals, but it has been ascertained that some of them certainly, and probably all, paralyse or kill the small mammals or other animals on which they feed.

The last few years too have shown that grooved teeth, connected with a poison gland occur in the mandible of a lizard (Heloderma), and this recurrence of the same kind of tooth in different positions, and in very distinct reptiles destroys the value of the character as evidence of genetic affinity. But if the distinction between poisonous and non-poisonous snakes is disregarded, the differences between harmless colubrines (Aglypha), such as Tropidonotus, and the forms with grooved teeth, like Dipsas or Homolopsis (Opisthoglypha), Naja or Elaps (Proteroglypha), are insufficient to justify placing them in separate subdivisions of the group.

Three years since, in his work on the Reptilia and Batrachia of British India, Mr. Boulenger rejected the old division of snakes into venomous and harmless, and proposed a new classification of the whole group founded on the characters of the skull, and the presence or absence of particular cranial bones. The occasion was a good one, for, singular to state, India is the only country in the world where all families of snakes are represented. Time only can show whether the present classification will stand; it is far from improbable that future discoveries may result in some modification of the system now adopted, but there can be not the slightest question that the principle is sound, and that the present system is a distinct improvement on its predecessors. The whole order of snakes is, by Mr. Boulenger, divided into the following nine families: (1) Typhlopidæ, (2) Glauconiidæ, (3) Boidæ, (4) Ilysiidæ, (5) Uropeltidæ, (6) Xenopeltidæ, (7) Colubridæ, (8) Amblycephalidæ, (9) Viperidæ.

Of these only three are generally known—(1) the Boidæ, containing the boas, pythons, and the curious Eryx, the two-headed snake of Indian jugglers; (2) the Viperidæ, which comprise ordinary vipers and Crotalinæ, (rattlesnakes and their allies); and (3) the Colubridæ, which play much the same part amongst snakes that the Passeres do amongst birds, and form a considerable majority of the living species. In the Indian list, out of 264 known snakes, 182, or about two-thirds, belong to the Colubridæ, and probably a similar proportion will be found to prevail throughout the world. The Colubridæ are in fact the dominant type of the present time. They are in all probability of comparatively recent origin, and the generic distinctions amongst them are frequently small and difficult to recognise.

Of the care bestowed upon the present work it is difficult to speak too highly. One instance may be quoted, as it illustrates the author's anatomical research, and at the same time shows the light thrown on other biological inquiries by accurate systematic knowledge. The snake fauna of Madagascar has long been known to present some remarkable peculiarities. The other reptiles and the batrachians of the Mascarene Islands are distinguished by the absence of many characteristic African families, and the presence of peculiar types, in so far conforming to the distinguishing features of the vertebrate fauna in general; whilst a few reptiles and batrachians exhibit remarkable relations to Indian genera on the one hand, and to South American on the other. The ophidians of Madagascar alone, including the Colubrine snakes, have been believed to belong almost wholly to South American genera. Mr. Boulenger, however, has ascertained that the Madagascar Colubrine species possess hæmal processes (hypapophyses) to the vertebræ, and are consequently generically distinct from their neotropical analogues, whilst some of the Madagascar Boidæ, belonging to what is very probably a family of more ancient origin than the Colubridæ, are of South American genera. Thus the Madagascar snakes agree with the lizards, tortoises, and frogs in their foreign relationships.

Nor has the thoroughness of the scientific work prevented due attention being paid to the details that are important as aids in the identification of species. The number of ventral and subcaudal shields is given for every specimen in the collection. Now as the ventral scutes alone are usually about 150 to 250 in different kinds of snakes, the mechanical work of counting them in nearly 3000 individuals (a few snakes have no ventral shields) catalogued in the volume before us may easily be conceived.

At a time when systematic zoology is not greatly studied by many biologists, and is even, it may be feared, despised by some of them, it is some satisfaction to point to the monographs that are issued from the British Museum as evidence of the work that is being done with the unrivalled collections there available for study. There is scarcely any branch of biological research in which the systematic relations to each other of different organised beings is not of importance, and if systematic biology does not represent the knowledge of the day, all biological studies are likely to suffer. It may fairly be doubted whether any branch of biological work demands greater scientific capacity, higher powers of generalisation or harder work than that of which Mr. Boulenger has afforded a good example in his Catalogue of Snakes.

W. T. BLANFORD.

AN ALPINE GUIDE.

A Handbook for Travellers in Switzerland. Eighteenth edition. (London: John Murray, 1892.)

IN the early days of mountaineering, when the Alpine climber wished to scoff at guide-books, he referred sarcastically to Murray's Handbook to Switzerland. It was so emphatically a *vade mecum* for middle-aged prosperity, and was more successful in limiting its information than in restricting its words. But times and editors have changed. The book for several years past has been up to the high standard attained by the other members of the series; and the edition of 1891, of which the present issue is a revision, even improves upon its predecessors. In the initials "W. A. B. C.," appended to the preface, it would be affectation not to recognise the name of one who unites a knowledge of the Alps, unique, perhaps, in its completeness, to an infinite capacity for taking pains.

We are told, and the book fully justifies the statement, that in preparing this edition, "every line of the text has been very carefully revised and corrected, the historical information having been considerably increased; the notices of the towns have been practically rewritten, particular attention having been devoted to their architectural monuments." The historical notices, indeed, are admirable models of terseness and clearness. That this is so, and that the information concerning the mountain districts has been brought quite up to date, while many places at present little known have been introduced to the notice of English travellers, is only what was to be anticipated in a book edited by Mr. Coolidge.

Six new maps of districts much frequented by English travellers form a special feature of this revised edition. One, of Zermatt, is on a scale of 1 : 50,000, while those of the environs of Lucerne, of Grindelwald, of the Upper Engadine, the Saasthal, and the district round Evolena, Arolla, and Zinal, are on half that scale. They are contoured at distances of 200 metres; the mountains are tinted brown, darkened as the height rises; the snows and glaciers are a pale blue. The maps themselves are excellent, but the tints do not produce a very satisfactory stereographic effect; indeed, we think that actually they have a contrary tendency. It may be that as the higher ground bears the darkened colour, and the snow region is almost white, the contrast is too violent. Be the cause what it may, the result is not quite a success. Still, notwithstanding this, the maps will be a boon to travellers. The introductory matter in this handbook is excellent, and we have observed only one omission. Avalanches, glaciers, structural geography are duly noticed, even natural history is not wholly forgotten, but geology is excluded. But in the course of two or three pages a general outline of the structure and geology of the Alps might have been given, and the attention of travellers called to the significance of the wonderful sections which are so often exhibited in Alpine regions.

We have dipped here and there into the two volumes, which include not only Switzerland, but also the Alps of Savoy and Piedmont, the Italian Lakes, and part of the Dauphiné, reading the accounts of the districts with which we are personally more familiar. Needless to say that we find them clear, accurate, and terse, yet full of information. The book, good before, is even better now, and cannot fail to be most useful to the British tourist.

T. G. B.

OUR BOOK SHELF.

A Handbook on the Steam Engine. By Herman Haeder, Civil Engineer. English Edition. Translated, with considerable additions and alterations, by H. H. F. Fowles, Assoc.M.Inst.C.E. (London: Crosby Lockwood and Sons, 1893.)

THIS is an excellent book, and should be in the hands of all who are interested in the construction and design of medium-sized stationary engines.

It is a real pleasure to find so much information gathered together, particularly when it is from the practical side of the subject. The number of text-books on the steam engine is legion, but few are of any use to the engineer as distinguished from the student.

The book appears to largely consist of notes accumulated both in the drawing office and in the works. These are of great value, and particularly so because all dimensions have been reduced to British units, thus rendering possible a comparison between Continental and British practice.

A careful study of the contents of this book and the arrangement of the sections, leads to the conclusion that there is probably no other book like it in this country. The volume aims at showing the results of practical experience, and it certainly may claim a complete achievement of this idea.

It must not be imagined from these remarks that the steam engine has not been treated in any other manner than that of rule of thumb, a term often used by those who would place theory before practice in the training of an engineer. Take, for instance, the diagrams intending to illustrate the defects in valve gears, which may often be met with in practice; these make the different defects perfectly clear, and one can see at a glance where the mistake is to be found.

Section x. deals with the calculations for power and steam consumption, and section xi. explains the effect of the inertia of the reciprocating parts of a steam engine; with an ordinary amount of mathematics all these can be easily followed. Section xiv. is on boilers. This section is the weak part of the book, and in future editions should be considerably augmented with information having reference to the design and strength of boilers.

The book is fully illustrated, in fact, we are told in the preface that the letter-press has been reduced as much as possible to allow of the introduction of the numerous tables and drawings; among the latter there is an excellent illustration of a compound Willan's central valve engine with two cranks—probably the best engine of the kind to be had. Some of these illustrations have evidently been especially prepared with the intention of giving an idea of principles of construction to the reader, particularly those having reference to types of steam engines, various ways of arranging cylinders and cranks in double and three-cylinders, compound, and triple expansion engine. These outline diagrams are exceedingly clear. Other illustrations are sectioned and finished in such a way so as to render the details evident. All these points add considerably to the value of the work as a text-book for senior students in our technical colleges; for draughtsmen engaged in stationary engine work, and for mechanic engineers generally.

N. J. LOCKYER.

Heat. By Mark R. Wright. (London: Longmans, Green, and Co., 1893.)

"OF making many books there is no end, and much study is a weariness of the flesh." Truer words than these were never written, and they are specially applicable at the present day. Mr. Wright's addition to the literature of science is avowedly "written specially to meet the requirements of the Advanced Stage of Heat as laid down in the Syllabus of the Directory of the Science and Art Department." To say that the author has satisfactorily accomplished his design is, therefore, to give him praise. In an examinational text-book there is little, if any, scope for originality, and all the author can do is to develop new methods of treatment. This Mr. Wright has done to a small extent, and he seems to be in touch with the work that has been done in connection with his subject during the last few years. Of the 136 illustrations only thirty-five have been drawn for the book: the majority of the others being of the well-known stock character, which have "had their day" and should have "ceased to be" long ago.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Slickensides.

IN the account of M. Daubrée's experiments on the geological work of high-pressure gas (NATURE, July 6, p. 228), the following sentence occurs:—"In any case it is perhaps a little difficult to understand how a *single* movement of one rock surface over another . . . could produce anything like a perfect polish."

This recalls to my mind a freshly-made fault I examined in 1890, in a pit at Longcliff, Derbyshire. The rock was a moist, sandy fireclay or gannister; an area of about 80 feet square, lying on a slope of 35°, had slid down some 3 or 4 feet. The operations at the foot of the slope removed the support of the mass of rock above the sliding plane, and shortly afterwards it split across the middle, and the lower portion moved about

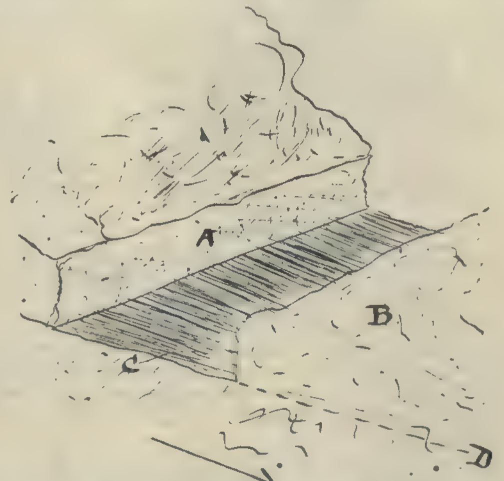

Diagram of fault at Longcliff Clay Pit.—A, Mass that slid down 4 ft. and then stopped: B, portion of A that slid 4 ft. further; C, Slickenside surface; D, fault or sliding plane.

3 feet further down, disclosing in the gap thus made the surface of the stationary rock. This surface exhibited every appearance of a typical slickenside; it was *highly polished*, *striated*, and even *blackened*, though the clay itself is cream-coloured. The striations corresponded with the direction of the movement, which had been a simple downward one.

Some slickensides may possibly be explained by reference to the action of high-pressure gas, but here at Longcliff was an unmistakable example of one caused by a "single movement of one rock surface over another," and it is very probable that the majority of ordinary slickensides have had a similar origin.

Mile End Road, London E., July 12. J. ALLEN HOWE.

Potstones found near Seaford.

PARAMOUDRA or potstones are known to geologists as existing in the chalk strata around Norwich and Belfast, but till lately I had supposed they were confined to those districts.

Last Whitsuntide, whilst enjoying a ramble along the chalk cliffs, east of Seaford, I was surprised to come across what seemed a real, but unusual potstone, lying among the stones below high-water mark, but which must, presumably, have originally fallen from the chalk above. Although consisting of a mass of chert, instead of pure flint like those near Norwich, in every other respect it resembles them. In form it is a large irregular cylinder and lies on its side, so that the sea water, when the tide rises, flows freely through it. It measures roughly between four and five feet in each direction, and the aperture has a diameter of twelve inches.

The enclosure of several large black flint nodules indicates that this peculiar shaped mass of chert has been formed since the flint itself segregated.

It seems probable that the "pipes" frequently found in sand will give us a clue as to its formation. In that case silica in the form of quartz is held together by ferruginous matter; here water holding silica in solution must have passed through the chalk like a vortex, and cemented together masses of chalk with its enclosed flints, with the result that we have a "pipe" of cretaceous matter held together by silica.

Here also, as on the Norfolk coast, are to be seen rings of flint on the shore, sometimes so placed as to form two or three concentric circles.

These instances, as well as others, point to the fact that masses due to segregation often assume the form of rings or cylinders. In flint this arrangement of growth is probably much more common than is generally known. I have already suggested (*Geol. Mag.*, June, 1893) a theory to account for the existence of these forms in flint, which, since Lyell's description of them, have been an enigma to geologists.

Tunbridge Wells, July 18. GEO. ABBOTT.

Simplified Multiplication.

THE object of this note is to explain a process of simplifying multiplication. To most people multiplication by 2, 3, 4, 5 is *sufficiently* easy (and not worth incurring any trouble to make easier); whereas multiplication by 6, 7, 8, 9 is decidedly more difficult, so is *sometimes* worth while simplifying.

Now, by admitting the use of *negative digits* (which may be marked by a minus sign placed over the digit), we may write—

$$6=10-4=1\bar{4},\ 7=10-3=1\bar{3},\ 8=10-2=1\bar{2},\ 9=10-1=1\bar{1},$$

This notation is pretty concise, being no longer than the ordinary notation whenever the extreme left-hand digit is <5, thus—

$$17=2\bar{3},\ 39=4\bar{1},\ 278=3\bar{2}\bar{2},\ 196=20\bar{4},\ \&c.$$

whilst it requires one digit more than the ordinary notation when the extreme left-hand digit is not <5, and is followed by a negative digit, thus—

$$99=10\bar{1},\ 789=1\bar{2}\bar{1}\bar{1},\ 676=1\bar{3}\bar{2}\bar{4},\ 5678=1\bar{4}\bar{3}\bar{2}\bar{2},\ \&c.$$

The preparation of a number so as to contain no digit >5 (by introduction of negative digits, each not >5) will be called (for shortness) *Reduction*: the process is so very simple that the "reduced" number can always be *written down at sight* (a most important matter).

To form the product P of two given numbers M, N, either one or both of the factors M, N may be "reduced" as a preliminary to multiplication. If both factors be reduced, the rule of signs of algebraic multiplication must be used, viz.

$$+\times+=+,\text{ and }-\times-=+\text{ ; but }+\times-=-,\text{ and }-\times+=-$$

This "reduction" of both factors is particularly useful when many large digits occur in succession in both factors, in which case the whole of the multiplication can often be done mentally (without even writing out at length), thus—

$$\begin{aligned}99^2&=10\bar{1}^2=10\bar{2}01=9801\\999^2&=100\bar{1}^2=100\bar{2}001=998001\\998^2&=100\bar{2}^2=1004004=996004\end{aligned}$$

The following factors become particularly simple by this "reduction," viz.

$$999\ldots9=1000\ldots\ldots\bar{1},\quad 888\ldots9=1\bar{1}\bar{1}\bar{1}\ldots\ldots\bar{1}$$
$$777\ldots8=1\bar{2}\bar{2}\bar{2}\ldots\ldots\bar{2},\quad 666\ldots7=1\bar{3}\bar{3}\bar{3}\ldots\ldots\bar{3}$$

When the results cannot be readily done mentally, the multiplication may be done by writing out at length *in the usual way* (attending of course to signs), thus—

$$\begin{array}{rr}89 & =1\bar{1}\bar{1}\\89 & =1\bar{1}\bar{1}\\\hline & \bar{1}11\\ & \bar{1}11\\ & 1\bar{1}\bar{1}\\\hline\end{array}$$
$$\therefore\ 89^2=1\bar{2}\bar{1}21=7921$$

$$\begin{array}{rr}789= & 1\bar{2}\bar{1}\bar{1}\\789= & 1\bar{2}\bar{1}\bar{1}\\\hline & \bar{1}211\\ & \bar{1}211\\ & \bar{2}422\\ & 1\bar{2}\bar{1}\bar{1}\\\hline\end{array}$$
$$\therefore\ 789^2=1\bar{4}22521=622521$$

It will be seen that the ease of the above procedure depends chiefly on the digits being so small (in both factors) as not to involve any *carrying* from digit to digit in the multiplications; this will always be the case when no digit exceeds 3 or $\bar{3}$ (because the greatest product $3\times3=9$ only). But when the digits 4, 5, 6 occur *in either factor*, this will usually involve *carrying* in the multiplications (because 3×4 and 2×5 are both >9). In this case it is generally better to "reduce" one factor only, and by preference that factor which has the greatest number of large digits (*i.e.* 7's, 8's, 9's), and further to use this factor as "multiplier," keeping the other factor unreduced as multiplicand. Further, it is often convenient in this case (especially when the factors are large) to completely separate the positive and negative products, add them separately, and finally take the difference of these sums; this will be the required product: this procedure (of using negative digits only in the multiplier, and then separating the + and − products) has the great advantages that (1) no further attention need be paid to the signs, and (2) the final line has all its digits necessarily positive, so is itself the required product (in ordinary notation).

Ex.—Given $M=34,892$, $N=89,795$; to find $M\times N$. Choose N as "multiplier," because it contains four large digits. The work proceeds thus—

$$\begin{array}{rl}34\,892 & =M\\1\bar{1}0\,\bar{2}\bar{1}5 & =N\\\hline 174\,460 & =5\times M\\3\,489\,2 & =1\times M\\\hline 3\,489\,374\,460 & =\text{Positive sum}=p\\\hline\end{array}$$

$$\text{All negative}\left\{\begin{array}{rl}348\,92 & =\bar{1}\times M\\6\,978\,4 & =\bar{2}\times M\\348\,92 & =\bar{1}\times M\\\hline 356\,247\,32 & =\text{Negative sum}=n\end{array}\right.$$

$$\therefore\ p\ldots n=3\,133\,127\,140=\text{Product }M\times N$$

It will be seen that this process requires two more lines than the ordinary process (viz. the two lines p, n), but the *actual multiplications are far easier.*

It is obvious that the two lines p, n may be separately tested by the usual processes of "casting out the nines, elevens, &c."

The whole process above is so simple that it might well find a place in works on elementary algebra immediately after the explanation of the rule of signs in multiplication; it is thoroughly practical, and having been much used by the author, can be confidently recommended.

The use of negative digits, as above explained, may also be applied to the process of division, and in some cases with advantage. This application is, however, in general by no means quite easy, so cannot be recommended as a practically useful process.

[This process—as applied to multiplication—is not of course new; but it seems worth while to attempt to revive it now; as a process, somewhat the same in principle, has just been published (in the *Annales des Ponts et Chaussées* for April 1893, p. 790) by Mr. Ed. Collignon. The only *actual multiplication* required in his process is by the digits 2 and 5; the elimination of actual multiplication by 3, 4, 6, 7, 8, 9 is of course an immense advantage. To this end he first shows how to "reduce" any number N to the algebraic sum (say $N_1+N_2-N_3$) of three others, N_1, N_2, N_3, composed solely of the four digits 0, 1, 2, 3. To multiply two numbers M, N, one of them, say N, is to be "reduced" as explained: the products MN_1, MN_2, MN_3 are then to be formed in the usual way; their algebraic sum $MN_1+MN_2-MN_3$ is the product required. The process has two decided defects, viz.—(1) the "reduction" of N is somewhat troublesome; (2) the forming and adding the three products ($MN_1+MN_2-MN_3$) is a good deal longer than the ordinary process.] ALLAN CUNNINGHAM.

Thunderstorm Phenomena on the Matterhorn.

IN 1888-1889 I witnessed some eight-and-twenty thunderstorms on the Pampas of South America; and came to the conclusion—

(1) That there was no reason to suppose that the so-called "sheet-lightning," or "summer-lightning," is anything more than the glare of distant spark-discharge;

(2) That by far the greater number of discharges took place between different layers of cloud, and not between clouds and the earth;

(3) That the origin of these storms lay in the electrical excitation due to the friction between opposed currents of air (carrying cloud), upper and lower respectively.

This year I was witness of a thunderstorm under very different circumstances, and I observed a phenomenon that appears to me to be of interest.

On July 10 I was on the Matterhorn in very doubtful weather. It appeared as though the Föhn (or southerly wind) were struggling with a northerly wind, and as though the former conquered. Clouds or mist pressed up from Italy, and rose higher and higher, covering the other mountains before the Matterhorn. We had some snow at intervals even before mid-day, and by the time that we had, on return from the summit, descended as far as the upper hut, it was snowing steadily. I think that, as regards the Matterhorn, the electrical hissing of ice-axes, rocks, &c., began about 3.30 p.m. or 4 p.m., and lightning began rather later.

At last came one flash, apparently very near to us, the thunder following close with a crash. *Before the thunder*, however, and apparently *with* the flash, came a curious splitting, cracking, and shivering sound, with a kind of "splash" from the rocks—as it seemed. I give many adjectives for want of one good expressive word. This sound preceded the thunder, and was both sharp and faint; I felt that I only heard it because I was on the spot.

Later, another flash came close to us. This time I heard no "splash" from the rocks; but, apparently *with* the flash, and before the thunder-crash, there came a light, shivering, branching crack again, something like the "ghost" of thunder, one might say. It reminded me this time of the shiver that passes over the surface of new snow, only very slightly crusted, when first broken in any part by the feet of a traveller. (Some climbers will know this sound; but I myself have only occasionally noticed it, and that only when I have been the first on a snowfield soon after a heavy fall of snow.) I received a slight shock in the head this time. A third flash gave the same sound as the second; but no others seemed so close, and I never heard this sound again.

It was dark when we reached the lower hut; and all down the arête the brushes of purple light that streamed from our fingers (when held up) and from our axes, hats, hair, &c., were very beautiful. The fingers gave better brushes when wetted. There were numerous brushes streaming from the rocks, these being wet with water melted from the snow.

Some other people who were on the Gorner Grat the same day told me, before I mentioned my experiences, that the lightning seemed to give a splashing sound on the rocks. They also told me that those who wore felt hats, felt return shocks, while those with straw hats did not. All the hats were wet.

So much for observation; now for a theory.

To begin with, since the thunder distinctly crashed *after* the lightning-flash, it would seem that the phenomenon that caused the sound I heard must have preceded the spark.

I would suggest the following explanation.

I do not think that those who have never been actually in a storm realise how very indefinite, in substance and boundaries, "a thundercloud" is. It seems certain that we must not regard it as if it were a polished conductor that is gradually charged until it sparks to earth or to other clouds. More probably there is a fall (or rise) of potential through the substance of the cloud itself. When the stress is too great, there is probably a breakdown along many paths in the form of the fine branching sparks observed when a Wimshurst is used without a condenser. This preliminary breakdown suddenly gives a very much larger potential-difference between the portion of the cloud-masses towards which it takes place; so suddenly in fact, that a spark-discharge occurs before more diffuse modes of readjustment can obtain. It seems to me that it is only by some such preliminary discharge from behind that such irregular "surfaces" as those of clouds could attain the condition requisite for the true spark. In something the same way we can pass a spark between two rough or pointed metal terminals by a sudden discharge through them, while we could not raise them in any slower way to the necessary condition.

According to this view, a slighter and more branching discharge in the body of a cloud would be the necessary preliminary to a regular flash; and the, relatively faint, sound of it would precede the "thunder" of the final flash. When once the flash occurs, resistance is much diminished, and the stress of the whole region is relieved through the path created.

An obvious objection to this view, however, will occur to many. "Would the time-interval be long enough? Would not the first sound be practically heard with the thunder, and be drowned in it?'

Another explanation might be, that (as is often the case with a Wimshurst or other machine) there are fainter, tentative, branching discharges that precede the bright spark. But, if this were the case, they should surely be heard in some cases before any spark occurs at all.

Finally, the sound, though it appeared to come out of the air, might have been due to the movements of the stones and rocks over the surface of the mountain, occurring when the stress was relieved. Such a sound might well reach one before the sound of the spark. WALTER LARDEN.

R. N. E. College, Devonport, July 24.

Highest Rainfall in Twenty-four Hours.

WITH reference to the paragraph quoted in your notes of this week's NATURE from the *Indian Planters' Gazette* of Jan. 28, 1893, the most elementary knowledge of Indian meteorology would suffice to show that the remarkable figure, 48 inches, supposed to represent the fall of a single night in January at Dehra Dun, is simply a misprint for 4·8. The entire rainfall of the winter season in no part of India exceeds one-half this amount, and I have no hesitation in declaring such a figure as 48 inches in twenty-four hours to be absolutely without precedent, and, in my opinion, so extraordinary at such a season, that, if it really were 48, it would require us to regard all existing Indian meteorological data with suspicion. Thirty inches in twenty-four hours has often been recorded at Chirapunji in June and July. Can any one show a single instance of even 20 inches in twenty-four hours at Dehra Dun?

Moreover, the whole annual supply at Dehra Dun is only 75 inches, while that of Chirapunji is 600 inches!

July 29. E. DOUGLAS ARCHIBALD.

Vivisection.

THE recent remarkable discoveries in connection with Myxœdema conclusively prove the value of vivisection as a means whereby human suffering may be alleviated, and only those who are blinded by ignorance or prejudice would dare deny that hundreds of sufferers from goître, and other distressing symptoms of cretinism, have obtained relief solely through experimental research upon animals. Inconsistency is closely linked to prejudice, and the greatest anomaly is the Anti-Vivisectionist who, while objecting to the alleviation of human suffering on the score of "cruelty to animals," enjoys and countenances, for the gratification of his or her own individual pleasures, the most horrible cruelty and torture to helpless creatures. Only a few of such cases now occur to me, and these I herewith append, but there are many others as disgustingly cruel.

Boiling lobsters, prawns, etc., *alive.*

"Whitening and tendering" veal by bleeding, and beating with sticks, the calf *while still living.*

Skinning and cooking eels *alive.*

Maiming, and shattering to pieces, pigeons and other birds ("sport"), hundreds dying a lingering death.

Hacking and mauling rabbits by gins.

Hounding to death harmless hares, and exulting over this torture ("sport").

Plucking feathers from *living* birds, and skinning *living* animals.

When every professed anti-vivisectionist undertakes to endeavour to put a stop to these, and similar cruelties, their sincerity will at least be visible.

Bournemouth, July 24. CECIL CARUS-WILSON.

A Correction.

IN my "Preliminary Note," as read at the Royal Society meeting, June 15 last (NATURE, vol. xlviii. p. 311), the first paragraph reciting "The laws connecting pairs of axes, by successive rotations round which a given displacement of a rigid body in space may be effected," should read: "If the first axis is taken arbitrarily in a plane parallel to that of the 'central axis,' and any given direction ζ' meeting it, to which latter the axis remains parallel, there is a direction determined to which its conjugate must be parallel, in the side common to three quadric cones the constants of which are functions of ζ' and the vectors defining the displacement and the position of the first axis."

The next two paragraphs will require slight modifications accordingly; and the last will, of course, be unnecessary.

I owe this correction to a correspondence with which Prof. W. Burnside, F.R.S., has favoured me since the meeting.

July 29. J. J. WALKER.

THE ASTRONOMICAL HISTORY OF ON AND THEBES.

In a previous article I have attempted to show that there was a considerable difference of astronomical thought between those, on the one hand, who built pyramids and temples facing true east and west and those, on the other, who built solar temples not oriented to the equinox, but rather, though not exclusively, to the solstice.

It was suggested that although in the matter of simple worship the sun would come before the stars; in *temple* worship the conditions would be reversed in consequence of the stable rising and setting places of the latter as compared with those of the sun at different times of the year.

Another suggestion was hazarded that sun temple-worship might have been an accidental result of the sunlight entering a temple which had really been built to observe a star; and that such temple sun-worship might possibly have preceded the time at which the solstices and equinoxes, and their importance, had been made out. I think it is possible to show that this really happened, and we owe the demonstration of this important fact to the Egyptian habit of having two associated temples at right angles to each other, because this habit justifies the assumption that at On the single obelisk which now remains not only indicates the certain existence in former times of one temple, but in all probability of two at right angles to each other.

But this is only one point among many to which one may appeal in approaching the study of the question. Another of great importance is brought before us in the masterly essay by M. Virey, entitled "Notices Générales," on the discoveries made at Der el-Bahari by MM. Maspero and Grébaut.

In his account of the confraternity of Amen and of the various attempts made by the Theban priests to acquire political power he refers to the action of Amenhetep IV. (Chu-en-Aten).[1]

In the time of Thotmes III. the alliance between the royal and the sacerdotal power was of the closest, and in no time of the world's history have priests been more richly endowed than were then the priests of Amen. Not content, however, with their sacred functions, they aimed at political power so obviously that Thotmes IV. and Amen-hetep III., to check their intentions, favoured the cults and priesthoods of On and other cities of the north. Amen-hetep IV. went further; he looked for alliances out of Egypt altogether, and entered into diplomatic relations with the princes of Asia, including even the king of Babylon. This brought him and the priests to open warfare. He replied to their anger by prescribing the cult of Amen. The name of Amen was effaced from the monuments, still the priestly party was strong enough to make it unpleasant for the king in Thebes, and to deal them yet another blow, he quitted that city and went to settle at Tell el-Amarna, at the same time reviving an old Heliopolitan cult. He took for divine protection the solar disc *Aton*, "which was one of the most ancient forms of one of the most ancient gods of Egypt, Rā of Heliopolis."[2] Now let us say that the time of Amen-hetep IV., according to the received authorities, was about 1450 B.C. The lines of the "Temple of the Sun" at Tell el-Amarna are to be gathered from Lepsius's map, the orientation is 13° north of west. This gives us a declination of 11° north, and the star Spica at its setting would be visible in the temple, and the sunlight at sunset would enter the temple on April 18 and August 24 of the Gregorian year.

Hence, then, the temple was probably built really to observe the sunset on a special day in the year. In this view how appropriate was the prayer of Aahmes, Chu-en-Aten's chief official.

"Beautiful is thy setting, thou sun's disk of life, thou Lord of Lords and King of the worlds. When thou unitest thyself with the heaven at thy setting, mortals rejoice before thy countenance and give honour to him who has created them, and pray before him who has formed them, before the glance of thy son who loves thee the King Khu-en-aten. The whole land of Egypt and all peoples repeat all thy names at thy rising, to magnify thy rising in like manner as thy setting."

Still perhaps more beautiful was the prayer of the queen.

"Thou disk of the Sun, thou living God! there is none other beside thee! Thou givest health to the eye through thy beams. Creator of all beings. Thou goest up on the eastern horizon of heaven to dispense life to all which thou hast created; to man, four-footed beasts, birds, and all manner of creeping things on the earth, where they live. Thus they behold thee, and they go to sleep when thou settest.

"Grant to thy son, who loves thee life in truth, to the lord of the land, Khu-en-aten, that he may live united with thee in eternity.

"As for her, his wife, the Queen Nefer-it-Thi, may she live for evermore and eternally by his side, well pleasing to thee; she admires what thou hast created day by day."[1]

Still the light of Spica would not enter it axially if the orientation is correct. This would have happened in 2000 B.C., that is 600 years before the time of Amen-hetep IV. This is a point which Egyptologists must discuss;[2] it is quite certain that such a pair of temples as those of which Lepsius gives us the plans could not have been completely built in his short reign, and they would not perhaps have been commenced on *heretical* lines in any previous reign during the 18th dynasty. It must therefore have been commenced before 1700 B.C., perhaps in the 17th dynasty In any case it was certainly finished by Chu-en-Aten.

But this "temple of the Sun" was not built alone. There was another at right angles to it, and while Spica was seen setting in one, a star near γ Draconis was rising in the other.

Remembering then that the temple attributed to Amen-hetep IV. pointed to Spica, let us recur for a moment to the temple conditions at Thebes. There, as we have seen, the temple of Mut is associated with one at right angles to it, facing north-west. The amplitudes are $72\frac{1}{2}°$ north of east and $17\frac{1}{2}°$ north of west. I have shown that the temple of Mut would allow γ Draconis to be seen along its axis about 3200 B.C. *I now state that* Spica *would be seen along the axis of the rectangular temple at the same time.*

We have next to consider what had taken place at Thebes, so far as we can trace it on the orientation hypothesis since 3200 B.C.; but to understand thoroughly what was done another reference to M. Virey's essay is necessary. One of the chief aims of the confraternity of Amen was to abolish the worship of Set, Sit, or Sutech, that is generically the stars near the north pole, and, as it can be shown, in favour of the southern ones. The temple of Mut was the chief temple at Karnak, in which the cult of the northern stars was carried on.

We can now realise what the Theban priests got Thotmes to do.

In his day the cult of Spica (the solar disc, Aton, Min, Khem), and γ Draconis (the Hippopotamus and Lion Isis) was supreme. The little shrine of the Theban Amen was enlarged and built right aross the fairway

[1] "Notices des Principaux Monuments Exposés au Musée de Gizeh," p. 260. 1893.

[2] Gizeh Catalogue, 1893, p. 68.

[1] Translated by Brugsch, "Egypt," p. 221.

[2] Since the above was written, Prof. Flinders Petrie has been good enough, in reply to an inquiry, to state his opinion that the temple was entirely built by Chu-en-Aten. Should this be confirmed, it may have been oriented directly to the sun, on the day named, or more probably built parallel to some former temple, for traces of other temples are shown on Lepsius' plan, and I presume Chu-en-Aten is not supposed to have built all of them.

of the temple of Mut, so that the worship was as effectively stopped as the worship of Isis was stopped at Pompeii by the town authorities (when it was prohibited by law), bricking up the window through which the star was observed.

Further, the shrine so restored was of such magnificence that the Spica temple, which had hitherto held first rank, became an insignificant chapel in comparison. Nor was this all. In order still to emphasise the supremacy of Amen, a third-rate temple was erected to Ptah.

We may now return to Amen-hetep's doings at Tell el-Amarna. The worship he emphasised there exactly resembled that which had in early times been paramount at Heliopolis. One based on it, but not identical with it, had been in vogue at Thebes from 3200 B.C. to the time of Thotmes, who, as the tool of the confraternity of Amen, intensified the solstitial worship, and did his best to kill that which had been based upon the Heliopolis cult.

The next question we have to consider is whether the researches at Heliopolis bear this surmise out. It is true we have but one poor obelisk, but let us see what we can make of it. As I have shown, the north and south faces bear 13° north of west—13° south of east. Amen-hetep or some one of the preceding kings of Egypt, when reintroducing the old worship at Tell el-Amarna orients the solar temple 13° north of west according to the data available. Now when we take the difference of latitude between Heliopolis and Tell el-Amarna into account we find that the same declination (within half a degree) is obtained from both.

I have elsewhere shown that there is good reason for believing that the original foundation of the temple at On dates from the time when the north member of the system was directed to α Ursæ Majoris. This was somewhat earlier than 5000 B.C.

Bearing in mind the facts obtained with regard to other similar rectangular systems, we are led to inquire whether at that date a temple oriented to declination 11° north was directed to any star.

We find that the important star Capella was in question.

Now so far in my references to stars no mention has been made of Capella. It is obvious that the first thing to be done on the orientation hypothesis is to see whether any other temple, and if of known cult so much the better, is found oriented to Capella. There is one such temple; it is the small temple of Ptah, just mentioned as having been erected by Thotmes. (Time of Thotmes III. 1600 B.C. Amplitude of temple ± 35° west of north = with hills 3° high $32\frac{1}{2}$° north declination; Capella 33° north declination about 1700 B.C.)

And now it appears there is another. During the year 1892 the officers of the Museum of Gizeh, under the direction of M. de Morgan, excavated a temple at Memphis to the north of the hut containing the recumbent statue of Rameses, and during their work they found two magnificent statues of Ptah, "les plus remarquables statues divines qu'on ait encore trouvées en Egypte,"[1] and a colossal model in rose granite of the sacred boat of Ptah.

These discoveries have led the officers in question to the conclusion that the building among the ruins of which these priceless treasures have been found is veritably the world-renowned temple of Ptah of Memphis. It may therefore be accepted as such for the purpose of the present inquiry, although it is difficult to reconcile its *emplacement* in relation to the statues with the accounts given by the Arab historians.

In January, 1893, Captain Lyons, R.E., was good enough to accompany me to determine the orientation of the newly uncovered temple walls. We had already, two years previously, carefully measured the bearings of the statues of Rameses. We found the temple in all probability facing westwards, and not eastwards, this we determined by a seated statue facing westwards; and its orientation, assuming a magnetic variation of $4\frac{1}{2}$° west—to be $12\frac{3}{4}$° north of west and the hills, in front of it, assuming the village of Mit-Rahineh non-existent, to be 50′ high.

Here, then, we get reproduced almost absolutely the conditions of the obelisk at Heliopolis in a Ptah temple oriented to Capella 5200 B.C.

We are driven then to the conclusion that the star Capella is personified by *Ptah*, and that as Capella was worshipped setting, Ptah is represented as a mummy. If this be so we must also accept another conclusion. That the temples both at Heliopolis and Memphis were dedicated to Ptah. About 5300 B.C. we seem almost in the time of the divine dynasties, and begin to understand how it is that in the old traditions Ptah precedes Rā and he is called "the father of the beginnings, and the creator of the egg of the Sun and Moon.[1]

What, then, was this worship which had been absent from Thebes, but which had held its own to the north to such an extent that Amen-hetep IV. went back to it so eagerly? It could not have been the worship of Capella as a star alone, for such worship had been provided for by Thotmes III. by building temple G. Nor could it have been the worship of Spica as a star alone, for in that case the precedent of On would not have been appealed to. We are driven to the conclusion that it was the worship of the sun's disc when setting, at the time of the year heralded by these stars, when it had the declination of 10° north. The dates on which the sun had this declination were, as already stated, about April 18 and August 24 of our Gregorian year. The former, in Egypt, dominated by the Nile, was about the time of the associated spring and harvest festivals.

So much for the Ptah mummy form of the Sun-God, to which the Theban priests erected no temples. There was still another, the worship of which existed at Thebes, but which they did their best to abolish by the intensification of the worship of Amen-Rā. I refer to the worship carried on in the temple oriented to Spica. This, there can be no doubt, was the worship of Min, Khem in ithyphallic mummy form. This was associated with the harvest home festival on May 1. (Amplitude of temple, $17\frac{1}{2}$ north of west, declination 15° = sun's declination on May 1.)

It seems, then, that the suggestion that *possibly* sun-worship existed before the solstitial solar worship is amply justified.

Now so far as my inquiries have yet gone, there is not above Thebes, with the single exception of Redesieh, any temple resembling the On-Thebes ones to which I have directed attention as having a high north-east amplitude.

Similarly, with one or two exceptions which may be late, there are no temples facing the south-east below Thebes.

In short, in Lower Egypt the temples are pointed to stars rising near the north point of the horizon or setting west of north. In Upper Egypt we deal chiefly with temples directed to stars rising in the south-east.

Here again we are in presence of as distinct differences in astronomical thought and methods of observation as we found among those who directed temples to the sun at the equinox, as opposed to those who worshipped that luminary at some other time of the year.

Now with regard to the northern stars observed rising in high amplitudes we have found traces of their worship in times so remote that in all probability at On

[1] New Gizeh Catalogue, p. 61.

[1] Brugsch, "Religion and Mytologie," p. 111. Pierret, "Salle Historique de la galerie Égyptienne" (du Louvre), p 199.

and Denderah α Ursæ Majoris was used before it became circumpolar. We deal with 5000 B.C.

Since undoubtedly *new* temples with nearly similar amplitudes (such as that denoted by M at Karnak) were built in late times, we find so long a range of time indicated that the utility of the stellar observations *from the yearly point of view* could scarcely have been in question.

It may be suggested therefore that the observations made in them had to do with the determination of the hours of the night; this seems probable, for in Nubia at the present day time at night is thus determined.

It may be that such stars as Canopus were used by the southern peoples for the same purpose as α Ursæ Majoris first and then γ Draconis were used by the northerners. In other words, the question arises whether the extreme north and south stars were not both used as warners of the dawn all the year round.

It is well known that in quite early times means had been found of dividing the day and night into 12 hours. In the day shadows cast by the sun, or sundials, might have been used, but how about the night?

We have seen that the Egyptians chiefly, if not exclusively, observed a heavenly body and the position of other bodies in relation to it, when it was rising or setting, so that it was absolutely essential that the body which they were to observe should rise and set. Everybody knows that as seen in England there are many stars which neither rise nor set. The latitude of London being 51°, the elevation of the pole therefore is 51°.

Hence, any star which lies within that distance from the pole cannot set, but sweeps round without touching the horizon at all. The latitude of Thebes being 25°, the distance from the pole to the horizon is much smaller, and so the number of stars which do not rise and set is much smaller. The stars which do not rise or set are stars near the pole, and therefore stars which move very slowly, and the stars which rise most to the north and most to the south are those bodies which are moving most slowly while they yet rise or set. Can this slow rate of motion have had anything to do with such stars being selected for observation, the brightest star to the north, most slowly moving, the brightest star to the south most slowly moving? It is possible that observations of these stars might have been made in such a way that at the beginning of the evening the particular position of γ Draconis, for instance, might have been noted with regard to the pole star: and seeing that the Egyptians thoroughly knew the length of the night and of the day in the different portions of the year, they could at once the moment they got the starting point afforded by the position of this star practically use the circle of the stars round the north pole as the dial of a sort of celestial clock. May not this really have been the clock with which they have been credited? However long or short the day, the star which was at first above the pole star, after it had got round so that it was on a level with it, would have gone through a quarter of its revolution.

In low northern latitudes, however, the southern stars would serve better for this purpose, since the circle of northern circumpolar stars would be much restricted. Hence there was a reason in such latitudes for preferring southern stars. With regard both to high north and south stars then, we may in both cases be in presence of observations made to determine the time at night. So that the worship of Set, the determination of the time at night by means of northern stars, might have been little popular with those who at Gebel Barkal and elsewhere in the south had used the southern ones for the same purpose, and this may be one reason why the Theban priests, representing Nubian astronomical culture and methods, were pledged to drive the cult of Sutech out of the land.

Since then the observations of γ Draconis might be used to herald the sunrise almost all the year round, and since the modern constellation Draco is the old Hippopotamus, we can readily understand Plutarch's statement that "Taurt presides over the birth of the sun," and why Taurt or Maut should be called the Mistress of Darkness.[1]

It does not seem too much to hope that the continuation of such inquiries may ultimately enable us to solve several points connected with early Egyptian history. We read in Brugsch:—[2]

"According to Greek tradition, the primitive abode of the Egyptian people is to be sought in Ethiopia, and the honour of founding their civilisation should be given to a band of priests from Meroë. Descending the Nile, they are supposed to have settled near the later city of Thebes, and to have established the first state with a theocratic form of government."

"But it is not to Ethiopian priests that the Egyptian Empire owes its origin, its form of government, and its high civilisation; much rather was it the Egyptians themselves that first ascended the river to found in Ethiopia temples, cities, and fortified places, and to diffuse the blessings of a civilised state among the rude dark-coloured population."

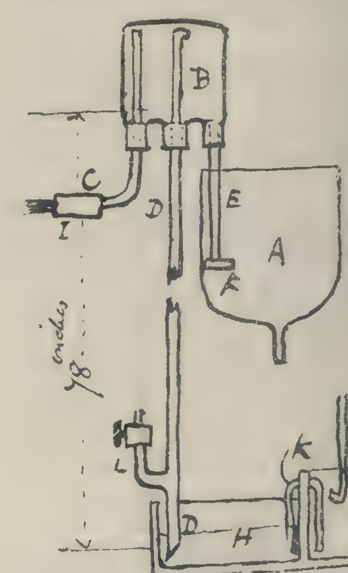
. . . "Strange to say, the whole number of the buildings in stone, as yet known and examined, which were erected on both sides of the river by Egyptian and Ethiopian kings, furnish the incontrovertible proof that the long series of temples, cities, sepulchres, and monuments in general, exhibit a distinct chronological order, of which the starting point is found in the pyramids, at the apex of the Delta."

J. NORMAN LOCKYER.

(*To be continued.*)

A PERIODIC MERCURY PUMP.

I HAVE designed and constructed the instrument described in the following lines to reduce the labour of working pumps of the Sprengel class. It has proved itself to be so serviceable in our laboratory that I believe a short descripion of it may be useful to those who



are engaged in work in which the mercurial pump is employed.

A is the cistern of the Sprengel pump (not shown), B is a bottle having three necks: it is furnished with three tubes, C, DD, EF; C, which has a valve at I, is attached

[1] Rawlinson, i. 337.
[2] "Egypt under the Pharaohs," ed. 1891, p. 3.

to an ordinary water-pump through a wash bottle containing sulphuric acid (I find that which is known as the University College pump the best); EF dips into the cistern A, and is closed at its end F by a small glass ball fitting the ground out end of the tube which acts as a valve. The tube DD dips in the cistern H into which the mercury from the Sprengel pump is discharged. The siphon K causes the supply of mercury to be periodic; upon this the action of the pump depends. By means of a stopcock L air is admitted to the tube DD. The mercury is raised thus: A partial vacuum is formed in B by the water-pump; this raises the mercury to the point where L joins DD; a piston of mercury is then formed, and it is at once carried up into B; this goes on till all the mercury in H is raised to B, then air is drawn through DD and the vacuum ceases in B, and the mercury falls through EF; in a short time H refills, and the operation is repeated.

The instrument at work in my laboratory raises 90 lbs. of mercury 6·5 feet high in one hour. The pump requires no attention after it has been started. The valve I stops the tube C, should the supply of water to the water-pump be accidentally cut off when the pump is lifting. I have made many experiments with mercury elevators, and from these it appears that the periodic supply of mercury to the cistern from whence it is drawn greatly contributes to the certainty of the action of the instrument.

FREDERICK J. SMITH.

THE LATE DR. JOHN RAE.

DR. JOHN RAE, F.R.S., whose death we announced last week, was perhaps the most persevering and successful of the Arctic travellers by land whose journeys called forth the admiration of the world forty years ago. He was a native of Orkney, born in 1813, and studied medicine at Edinburgh, where he qualified in 1833. Rae was early brought face to face with his life-work, his first engagement on leaving college being as surgeon to the Hudson Bay Company's ship which carried supplies to the fur-forts in Hudson Bay. He entered the service of the company, and for ten years lived at Moose Factory, gaining familiarity with Arctic life during the severe winters. In 1845 his true career as an Arctic explorer began in his undertaking the leadership of a small expedition to explore a considerable extent of the coast-line of the Arctic Sea. In June, 1846, he set out on this expedition from York Factory, coasted along the west side of Hudson Bay, and wintered on the shore of Repulse Bay. Early in 1847 he made an extensive land journey to the north and west, with the result that 700 miles of new coast were surveyed, almost filling the gap between Ross's work in Boothia and Parry's at Fury and Hecla strait. In 1850 Dr. Rae published an account of this expedition in the form of a book of 250 pages. This was, curiously enough, his only permanent contribution to geographical literature, his subsequent journeys being recorded merely in formal reports published in the *Journal* of the Royal Geographical Society. After this journey Rae came to London, but was almost immediately induced to join the first land expedition sent to seek for Sir John Franklin, under the leadership of Sir John Richardson. The expedition was unsuccessful as to its primary purpose of finding traces of Franklin, but it effected a satisfactory survey of the whole coast between the Mackenzie and Coppermine rivers. In 1851 Rae received the command of another boat expedition for the Hudson Bay Company, in the course of which he thoroughly explored and mapped the south coast of Wollaston Land and Victoria Land, still searching vainly for traces of Franklin's party. On his return from this arduous undertaking, which he conducted throughout with conspicuous daring and sagacity, he had to travel on snow-shoes, and himself dragging a sledge, across the whole length of Canada from the Arctic Sea, through Fort Garry (now Winnipeg) until he reached United States territory. His total walking on this expedition was over 5000 miles, of which 700 miles were traversed for the first time. On returning to England in 1852 the gold medal of the Royal Geographical Society was presented to him by Sir Roderick Murchison in a speech, the cordial terms of which showed how fully Dr. Rae's genius for Arctic travel with the minimum of equipment and at infinitesimal expense was appreciated by the highest authorities. In no wise deterred by the hardships of his earlier campaigns, Rae left England early in 1853 to continue his work in the far north; the Hudson Bay Company equipping an expedition on condition that he would lead it personally. He completed the survey of King William's Land on this occasion, proving it to be an island; 1100 miles of sledging were accomplished in the process, of which 400 miles were new discovery. But the really important result of this expedition was Dr. Rae's meeting with the first evidence of Sir John Franklin's fate, from the story of a party of wandering Eskimo. The tribe encountered were in possession of many personal relics of members of that ill-fated expedition, which Rae secured and brought home. When he returned to England with the news so long searched for and so anxiously awaited, the Admiralty, which had spent large sums in fitting out successive expeditions, concluded that the fate of Franklin was decided beyond a doubt, and accordingly awarded to Dr. Rae the sum of £10,000 offered by Government to the first who brought back decisive information. The justice of this award was at the time strongly objected to by Lady Franklin, and although no further action was taken by Government she continued to organise private expeditions, which, while proving in effect the correctness of Dr. Rae's information from the Eskimo, served in no small degree to advance the geographical survey of the polar area.

In all his expeditions, Dr. Rae made collections of characteristic plants and animals as well as physical and meteorological observations. The material, described by other workers, went to swell the sum of our knowledge of the general conditions of climate and life in the Arctic basin.

In 1860 and subsequent years Dr. Rae made a series of interesting journeys in Iceland, Greenland, and in North America with the object of exploring and arranging routes for telegraph lines. His later years were spent in this country, where he made himself conspicuous by his zeal in forwarding the volunteer movement, being himself an excellent shot. The feeling which grew upon him to a painful extent as he became older, that his brilliant explorations were not adequately recognised and acknowledged on the Admiralty charts, unfortunately somewhat embittered his last years. But to the end he took the keenest interest in Arctic travel and was ever ready to take part in discussions bearing on the region in which he had lived so long and suffered so much. He was a regular attendant at meetings of the Royal Geographical Society and Colonial Institute, and for many years attended the gatherings of the British Association.

NOTES.

THE Senate of Edinburgh University has conferred the honorary degree of Doctor of Laws upon Prof. Arthur Auwers, in recognition of his astronomical labours. The same honour has been given to Dr. Littlejohn, the President of the British Institute of Public Health.

A Reuter's telegram states that a cloud-burst occurred at Pueblo, Colorado, on July 28, and destroyed property to the value of 25,000 dols. Seven lives were lost. The Arkansas River for many miles was turned into a raging torrent. The buildings along the river, comprising small boarded shanties, tents, and houses occupied by workmen, proved an easy prey to the rising waters. The storm extended over a large area, and at Denver the electric street cars were prevented from running by the electrical disturbances.

We are glad to see that an attempt is being made to bring together members of the Royal and learned societies by the formation of a club in which membership will be limited exclusively to presidents, members of council, fellows, and members of the principal Royal and learned societies of the United Kingdom, India, and the colonies, academicians and associates of the Royal Academies, together with the presidents, members of convocation, council, and professors of the Universities and various Royal institutions. The club has already been joined by many distinguished men in science, art, and literature, and forty societies are represented either by past presidents, vice-presidents, presidents, and members of council. Premises comprising the whole of the block No. 63, St. James's Street, have been secured for the club house, which is expected to be ready for occupation early in October. The temporary offices are at 3, Waterloo Place, Pall Mall. Colonel W. P. Hodnett is the hon secretary.

The sixty-first annual meeting of the British Medical Association commenced at Newcastle-on-Tyne on Tuesday. The committee on hypnotism presented a report stating that they had satisfied themselves of the genuineness of the hypnotic state, but, after a discussion, the congress decided to receive the report without adopting it. In the evening Prof. Philipson, of Durham University, delivered an address, in which he described the diseases prevalent among mining populations, and suggested means by which to improve the machinery for guarding public health.

The Congress of the British Institute of Public Health met on July 27 at Edinburgh, and the Presidential address was delivered by Dr. Henry D. Littlejohn. On the following day Mr. Ernest Hart read a paper on "Cholera Nurseries and their Suppression." Mr. Hart claims to have established on a basis of evidence collected from every part of Europe the dicta—founded upon the original investigations by Snow and Simon on the British epidemics of 1848 and 1854, and by himself and Radcliffe of the East London epidemic of 1866. 1. "That cholera is a filth disease, carried by dirty people to dirty places, and diffused by specifically poisoned water." 2. "That you may eat cholera and drink cholera, but you cannot catch cholera." 3. "That cholera may be considered for all practical purposes as an exclusively water-carried disease, and that it is carried only by water poisoned by human discharges." Mecca is the nursery of cholera, holds Mr. Hart, and is the place in which to stop it. He formulates the following steps which ought to be taken to save the Mohammedans from the danger caused by their pilgrimages, to save the world from the danger caused by Mecca. 1. The Indian sanitary services should be re-organised. 2. A complete sanitary regulation of all Indian fairs should be undertaken, the precautions so successfully instituted at Hurdwàr in 1891 being taken as a type. 3. A rigid system of medical inspection of all pilgrims should be instituted at the ports from which they start, the sick being detained and the healthy alone allowed to proceed. This, it may be added, would be all the more effectual in regard to Indian ports from the fact that a second weeding out of the infected can take place at Camaran. 4. The medical inspection at Camaran should be so conducted as to ensure its complete efficiency. A large number of communications were read in the various sections, but the majority of them were not of general scientific interest. The congress was brought to a close on the afternoon of July 31.

In the August number of the *Entomologist's Monthly Magazine* Lord Walsingham gives a description of the manner in which the late Mr. Stainton's collection of *Lepidoptera* have been disposed by the Trustees of the British Museum to whom they were presented. The collection is now accessible to students at the Natural History Museum. With regard to a large cabinet containing a great number of European and exotic *Tineidae*, Lord Walsingham writes: "It has been determined, after making an inventory, to keep the contents of this cabinet for the present undisturbed, although it is hoped that they may be incorporated from time to time in the future together with other material: for instance, my own collection (including that of the late Prof. Zeller) left by my will to the Museum; the *Grote* collection, still untouched as regards the *Tortricidae* and *Tineidae*; and the Frey collection, lately purchased by the trustees."

In a letter to the *Times* the Vicar of Selborne solicits subscriptions in order to supply water to the village from the well-head eulogised by Gilbert White. The sum required to do this is only £300, of which about £30 has been collected. A Selborne water supply would be an excellent memorial to White, and there should be little difficulty in raising the modest amount which would lead to its realisation.

The Institution of Mechanical Engineers opened its summer meeting, on Tuesday, at Middlesbrough, under the presidency of Dr. W. Anderson, and a discussion took place on recent developments in the Cleveland iron and steel industries.

A meeting of the Yorkshire Naturalists' Union will be held at Hellifield on August 7, for the investigation of the valley of the Ribble from Gisburn to Sawley Abbey.

It must be gratifying to writers in English journals of science to know that their literary labours are read and appreciated on the other side of the Channel. The current number of a French scientific journal of some standing contains translations of two articles that have appeared in these columns, running altogether into nearly six pages. There are also eight notes which have the same derivation. Every one knows that the code of journalistic ethics is more respected in the breach than the observance, yet it is rarely that one journal reprints an article which has appeared in another without acknowledging the original source. However, even the briefest form of acknowledgment is omitted in the case of the articles and notes to which we have referred. This is probably unintentional, for no editor with any regard for the reputation of his journal would purposely omit reference to his contemporary, though he might, of course, overlook the omission.

Though the feathered tribe of St. James's Park pass an existence remarkably free from danger, their lives are not without vicissitudes, if one may judge from a letter by Mr. T. Digby Pigott to the *Times*. It appears that on July 8 a dabchick's nest broke from its moorings in the dipping boughs of a black poplar, and drifted into the open. For twelve days the hen bird, who was sitting on the nest at the time of the accident, was buffetted about on the waters, yet she remained at her post. Her constancy received a reward which she doubtless regarded as sufficient recompense for all the anxiety, for she floated safely back to the place where her raft was built with two newly-hatched balls of down on her back. Was there ever a dabchick that had such a happy return from so long and adventurous a voyage?

A violent sandstorm occurred at Bärwalde, Pomerania, in the afternoon of April 30 last. A correspondent writing to *Das Wetter* for June states that after a fairly bright morning, with a light wind from south-east, the wind suddenly shifted to south-west, accompanied by heavy rain clouds. At about 2 p.m. some reddish-grey bands, such as are usually seen with hail-storm clouds, were observed, and rapidly spread over the sky. The whole air was literally filled with sand which the storm had apparently carried from a mountain about half a mile distant, and objects a hundred paces off were almost invisible. The phenomenon only lasted five minutes, after which time rain fell and cleared the atmosphere.

Although some large amounts of rain have fallen in part of these islands during July, the month, as a whole, has not been exceptionally wet. The greatest excess has been in the south of England, where the fall amounted to about 2·5 inches above the average; at Cambridge the excess was 1·4 inch, and in the north of Scotland 1·3 inch. In parts of the country, however, the stations reporting to the Meteorological office showed a considerable deficiency, amounting to 1·11 inch at Holyhead, 1 inch at Leith, and 0·9 inch at Yarmouth and Valencia, while in the neighbourhood of London the deficiency was about 0·3 inch. The temperature recorded at Greenwich for the month was 2° above the average of the last 50 years; on five days the readings exceeded 80°.

The Royal Meteorological Institute of the Netherlands has issued the second part of an atlas of observations made in the Indian Ocean, for the months of March, April, and May, the part for the first quarter having been published about three years since. The work has been drawn up with great care, the observations having been carefully examined for instrumental errors, and the data supplied by their own observers have been supplemented by observations from the London Meteorological Office, so that the results are both reliable and fairly complete. Among the principal charts we may mention those of the surface temperature of the sea, in which the limits of the warm and cold currents are clearly marked, especially to the south of the Cape of Good Hope. The currents of the ocean are represented by six charts, showing in two colours the observations plotted in position, and also arrows showing the general drift. The isobaric curves show a certain regularity in the monthly changes; for instance, there is a small centre of high pressure, 30·2 inches, in March, between 33° and 38° S. lat., and 87° and 91° E. long., while the isobar of 30·1 inches only extends from long. 82° to 102° E. In April this isobar extends over the whole Southern Indian ocean, from Africa to Australia; that of 30·2 inches also extends over the same area, while a centre of 30·3 inches is found at lat. 30° S., between 90° and 95° E. long. In the month of May the conditions are nearly similar to those of March; the centre of 30·3 inches has disappeared, the isobars of 30·2 inches and 30·1 inches lie more to the north, and another centre of 30·1 inches is formed, which extends from the coast of Africa to 75° E. long. The charts of air temperature are very similar to those of the sea-surface temperature, the temperature of the air being rather lower than that of the water.

The success which followed Loeffler's attempt to root out the mouse plague in Thessaly by means of his *bacillus typhi murium* has not apparently been so uniform in other and similar epidemics. But Loeffler, although quite recently acknowledging its failure in some cases, does not attribute this to any shortcomings in his bacillus, but rather to the lack of care and intelligence in those entrusted with the carrying out of the plan of campaign. The question has been reopened quite lately by the publication in a Stuttgart paper of some investigations made by Lüpke on the efficacy of Loeffler's microbe. According to these researches, the bacillus in question is not endowed with all the virtues which have hitherto been ascribed to it, and Lüpke states that although in his experiments weakly mice succumbed, some rapidly, and some only at the end of fifteen days after being fed with it, vigorous specimens invariably resisted its action, and, further, were rendered immune, so that even subcutaneous inoculations of the bacillus failed to destroy them. In consequence of these results Laser (*Centralblatt f. Bacteriologie*, vol. xiii. May, 1893) has brought forward an organism, *bacillus der Mäuseseuche-Laser*, which he isolated during an epidemic which broke out amongst the mice kept for experimental purposes in the hygienic laboratory at Königsberg. This bacillus threatens to become a formidable rival to Loeffler's microbe, for, apparently, whilst its action on field mice is more rapid and more certain than the latter, it is quite as harmless to other animals such as horses, guinea-pigs, pigeons, cats. The experiments require, however, further expansion and confirmation, and it is to be hoped that Laser will pursue his investigations, which may lead to the discovery of a satisfactory means of suppressing the farmers' *bête-noire*.

It has been proved during the last few years that at depths of more than 100 fathoms, the water of the Black Sea contains so much sulphuretted hydrogen that it is totally unfit for organic life. The amount of sulphuretted hydrogen increases with depth, and attains 655 cubic centimetres in one hundred litres at a depth of 1185 fathoms. In order to determine whether this gas is a product of micro-organisms, samples of ooze, which had been brought to the surface by Thomson's apparatus from various depths of 16, 40, 389, 870, and 1207 fathoms, have been carefully analysed at the Odessa bacteriological station. The analyses show that the ooze contains several different species of micro-organisms, all of which are capable of producing sulphuretted hydrogen. One of these is endowed with this capacity to a high degree. Its dark coffee-coloured pigment gradually becomes black when the microbe is cultivated on agar-agar with free admission of air; but its elongated, mobile rods an live under anaërobic conditions as well, and in such a case the exhalation of sulphuretted hydrogen is increased. The name of *Bacillus hydrosulfuricus Ponticus* has been given to the microbe. Further research has proved that the bacillus remains active, not only in cultures of albumen substances, but also in such as contain no sulphur of organic origin, but only mineral sulphates (gypsum), and sulphites. The multiplication of this bacillus thus does not require an accumulation of considerable amounts of decaying animal matters at the bottom, for it lives chiefly upon the cellulose of vegetable remains, and breathes the oxygen of the sulphates of mineral origin which it decomposes.

Six samples of ice obtained from London depôts and restaurants have been subjected to chemical and bacteriological analysis in the *Lancet* laboratory. The outcome of the inquiry is stated as follows:—"(1) By far the greater proportion of ice supplied in London is natural (generally Norwegian). Of the specimens procured only one had been produced artificially, and this specimen gave indifferent results on chemical analysis, but results of an eminently satisfactory kind in the light of bacteriological inquiry, practically no development of colonies of organisms taking place on culture. (2) Two out of five specimens of ice imported into this country from Norway, whilst yielding a satisfactory chemical analysis, were decidedly bad according to bacteriological examination, the number of colonies of organisms counted on culture varying from 400 to 700 per cubic centimetre of the melted ice. (3) Three out of five specimens of imported ice, though furnishing no condemnatory evidence on chemical examination, yielded bacteriological results such as might under certain circumstances give rise to suspicion, though they may be regarded as of fairly good quality." It is therefore urged that ice for table use should always be produced by the artificial freezing of freshly-distilled or sterilised water.

In the "Monthly Report of the Maryland State Weather Service" for May, 1893, Prof. W. B. Clark again refers to "The Leading Features of Maryland Climate" (see Nature, vol. xlvii. p. 585), giving tables of temperature, rainfall, &c. The same parallels of latitude show great variations in climate due to the complexity of the surface configuration.

In the same Report Prof. Clark describes "The Available Water-power of Maryland," only a small portion of which is at present utilised. Most of this occurs in the Piedmont Plateau, the central area of Maryland bounded by the Coastal Plain and the Appalachian Region. The north fork of the Potomac, draining an area of about 1300 square miles, has a maximum discharge of over 700 times its minimum. This great variability, which is nearly fatal to the extensive use of water-power on this river, is attributed to the absence of lakes, the steepness of the mountain-sides, and the narrowness of the valleys. Some of the tributaries of the north fork are fairly constant in flow.

We learn from the *Botanical Gazette* that the University of Minnesota has established an inland biological station at Gall Lake, in Minnesota. The laboratory of marine biology of the University of Pennsylvania, at Sea Island City, New Jersey, is now open for its third summer session. The same journal informs us that Baron von Müller is intending to publish a volume which shall complete Bentham's "Flora Australiensis."

Messrs. Krigar Menzel and Raps have contributed another instalment of their work on the motion of vibrating strings to the Prussian Academy of Sciences. Their beautiful experiments on the continued vibrations of bowed strings have been supplemented by the photographic study of the peculiar motions exhibited by plucked strings. To confine the vibrations strictly to one plane, and also to control the instant of exposure, a special plucking apparatus was designed. The string was kept resting against a small plate in the vertical plane by means of a hook which could be released by pressing upon a lever. The motion of the lever also closed a circuit which released the instantaneous shutter of the camera. The wire vibrated in front of a slit illuminated by an arc light, an image of the slit being projected upon the wire so that the screen of the camera showed a well-defined bright slit interrupted by a dark spot where it was crossed by the wire. This dark spot would vibrate during the oscillation of the string, and a trace of its motion was obtained by receiving the image upon a revolving drum covered with bromide emulsion paper. The point at which the string was plucked was determined by observing the interval between the sounds emitted by the two parts on either side of the hook. Different vibrating points along the string were photographed, and beautiful white-on-black traces were obtained. The general type of these is represented by a zig-zag line with straight flat portions at the top and bottom of each wave. All the component lines are straight, showing that the point of the string moved from one extreme of displacement to the other at constant velocity, then had a period of complete rest, and afterwards returned to the first position, again at constant velocity. As the vibrations succeeded each other, the top and bottom portions gradually slanted towards the middle, some of them showed ripples, and the up and down lines exhibited a slight convexity towards the left, *i.e.* the past. The authors further showed that all these observations are to be explained by the accepted theory of the vibration of strings, as worked out by Kundt and others.

The last number of the *Journal* of the Institute of Electrical Engineers contains an important paper by Mr. W. B. Sayers on the prevention and control of sparking; continuous-current dynamos without winding on the field magnets, and constant-pressure dynamos without series winding. Both Mr. Swinburn and Mr. Esson have given expressions for the maximum load, which can be carried without sparking, in terms of the ampere-turns upon the armature, the length of the air-space, the angle subtended by the polar surfaces of the field magnets, and the forward induction. Thus in ordinary ring and drum armature machines the considerations of sparking limit some of the most important elements in the design of the machine. So that the lightening of machines by putting the conductors in tunnels, reducing the air-space to a mere clearance, which is the condition in which minimum exciting force is required, has not been hitherto practicable. In order to secure the sparkless reversal of the commutator section under the collecting brush at any desired place between the horns of the pole-pieces, the author has designed a machine whose chief peculiarities are as follows:—The air-space is a mere clearance—one millimetre. The reversal of the sections is effected by inductors, or coils, which he calls commutator coils, and are independent of the winding. These commutator coils are not inserted in the closed or re-entrant circuit of the ring or drum, but are inserted in the connections that run at intervals from the re-entrant winding to the several bars of the commutator. The function of these coils is to furnish electromotive forces that will balance those due to back-induction and self-induction in the sections as they are successively reversed. These commutator coils are so arranged as to be acted on by the pole-tip which is strengthened by the armature current, and the brushes of the machine when run as a generator are set with a backward lead instead of a forward one. These auxiliary coils also permit of the reversal of the armature sections just after they have emerged from under the strengthened pole, the result being that those turns of the armature which have hitherto been called back turns become forward turns, and the effect of the cross induction is to increase the reversing field instead of to diminish it. The machine is self-exciting by means of the armature windings only, that is, it generates a current without any winding on the field magnets, which may, therefore, more properly be called keepers, and runs absolutely without sparking at the brushes.

Apparently Humboldt's description of the combats designedly brought about between wild horses and electric eels, in order to effect the capture of the latter, has to go the way of many others. A writer in the *Spectator*, who has travelled on the llanos of Caracas—the scene of Humboldt's account—says that he failed to find any confirmation of this method of capture. He adds that those who have investigated the matter have come to the conclusion that *trembladores*, as the eels are termed, could not be taken with the help of horses. The method of capture usually adopted is by nets, and it is found that by wearing indiarubber gloves, the fish can be handled with impunity.

The *Photographic Annual* for 1893, edited by Mr. Henry Sturmey, has been published by Messrs. Iliffe and Son. It is a remarkably fine production, and contains a vast store of information of interest to all concerned with photography and its various applications. Among articles of bibliographical importance we note one on the progress of photographic chemistry during 1892, by Mr. C. H. Bothamley, and Mr. Albert Taylor's concise description of all that was done in astronomical photography during the same year. Photography in relation to meteorology is the work of the late Mr. G. M. Whipple; and Mr. Chapman Jones is responsible for a portion of the volume devoted to photographic optics. In addition to this section on the making of photographic history, there is one containing articles on "Practical Subjects by Practical Men," which consists chiefly of "dodges" devised by devotees of the art. Numerous excellent specimens of half-tone engravings embellish the pages of the book, and render it one of the best publications of its kind. Another excellent work of the same kind as the preceding is the "Annuare Général de la Photographie," published under the auspices of the International Union of Photography and the National Union of Photographic Societies in France. Some of the illustrations in it are marvellous examples of photographic reproduction.

MESSRS. SIMPKIN, MARSHALL, AND CO. have published a pamphlet by Mr. John Sime containing an account of the work of Sir Francis Ronalds, F.R.S., in connection with electric telegraphy. In an essay, entitled "Descriptions of an Electrical Telegraph," published as early as 1823, Ronalds gave an account of his experiments in sending signals through a line of overhead wires erected in 1816 in the garden of the house at Hammersmith now occupied by Mr. William Morris, the distinguished poet. A tablet commemorating the fact has been placed on a wall of the house. Says Mr. Sime—"Twenty years before Wheatstone and Cooke or Morse had patented their improvements in the telegraph—indeed, while the first two were respectively lads of twelve and fourteen years of age—Ronalds had sent messages over *eight miles* of overhead wires of his own construction, and had laid and worked a serviceable underground line of telegraph of sufficient length to demonstrate the practicability of communication by telegraph between long distances."

THE first part of "A Study of the Languages of Torres Straits," with vocabularies and grammatical notes, was read before the Royal Irish Academy two years ago by Mr. Sidney H. Ray and Prof. A. C. Haddon. The paper has been reprinted, and is published by the Dublin University Press. It is of scientific importance, because a study of the languages in the neighbourhood of Torres Straits must throw some light on the relations between Papuans and Australians. The three Papuan languages of the district with which the authors deal are (1) the Miriam; (2) the Saibai; (3) the Daudai.

MR. AUBREY RICHARDSON, a son of Sir B. W. Richardson, F.R.S., has brought together the ancient and modern law relating to cremation, together with the rules and regulations of various cremation societies at home and abroad, in a book entitled "The Law of Cremation," published by Messrs. Reeves and Turner. All interested in the legal aspect of cremation would do well to obtain it.

TWO more volumes of the excellent series of reprints being published by Engelmann, of Leipzig, have been issued. No. 41 is Dr. Kölreuter's "Preliminary notice of some experiments and observations on the Sex of Plants" (1761–1766), and No. 42 contains a communication made by Humboldt and Gay-Lussac in 1805 on "The Volume Law of Gaseous Compounds."

THE annual report of the Connecticut Agricultural Experiment Station for 1892 has been received. Among the investigations carried on during the year, was one dealing with the chemical composition of different parts of the tobacco plant in different stages of growth, and another on the chemical changes which take place in tobacco during the fermentation in the case.

MESSRS. W. COLLINS, SONS, AND CO. have issued an "Acoustics," by Mr. W. Lees. It is an extension of the portion devoted to sound in the author's book on "Sound, Light, and Heat," and is adapted to meet the requirements of the new syllabus of the Science and Art Department.

"ELECTRICAL ENGINEERING"—an illustrated monthly magazine published in Chicago—gives in each number an excellent synoptical index of current electrical literature.

A NEW edition of "Practical Solid Geometry," by Mr. J. Payne, that has just been published by Mr. Thomas Murby, contains, in addition, a section on graphic arithmetic and statics by Mr. J. J. Prince.

MESSRS. CHARLES GRIFFIN AND CO. have issued a second edition of Prof. Grenville A. J. Cole's useful book, "Aids to Practical Geology."

WE have received the second volume of "Faunæ Mediterraneæ," in which Mr. J. C Carns continues his descriptive lists of animal life in the islands of the Mediterranean Sea.

THE Museum and Laboratory report of the Colonial Museum and Geological Survey of New Zealand has been issued.

AN interesting memoir upon the action of liquefied ammonia on the anhydrous chlorides of chromium and iron is contributed by Prof. Christensen, of Copenhagen, to the *Zeitschrift für Anorganische Chemie*. The products of the reaction in the case of chromium are two of the best known of the remarkable ammoniacal compounds of that metal, namely those to which the somewhat formidable names of purpureo- and luteo-chromium chloride have been given, which compounds have consequently now for the first time been obtained by direct synthesis. Purpureo-chromium chloride may be represented empirically by the formula $CrCl_3 . 5NH_3$; its constitution, however, is usually represented as $ClCr . 5NH_3 . Cl_2$, inasmuch as two of the chlorine atoms are much more readily replaceable than the third. The compound crystallises in small carmine-red octahedrons. Luteo-chromium chloride contains one more molecule of ammonia in its composition; it is represented empirically by the formula $CrCl_3 . 6NH_3$. It is a very soluble substance, but yields a precipitate of the nitrate with nitric acid, which takes the form of lustrous yellow plates. The synthetical experiments of Prof. Christensen were briefly as follows:—A small quantity of violet chromium chloride, previously thoroughly dried at 100°, was placed in a small glass beaker immersed in a freezing mixture consisting of solid carbon dioxide and ether, and liquid ammonia (NH_3) was slowly added to it. No reaction was found to occur at this temperature, but upon removing the beaker and contents from the freezing mixture and warming it with the hand, at the moment when the temperature approached that of the boiling-point of ammonia ($-38°·5$), a sudden interaction took place, accompanied by a hissing noise, and resulting in the conversion of the chromium chloride into a red mass largely consisting of the purpureo-chloride. The excess of ammonia was usually eliminated as gas, but if a very large excess was employed a portion of it remained as unchanged liquid capable of reacting with a further quantity of chromic chloride. At the conclusion of the reaction the product was washed with cold water and hydrochloric acid, finally dissolved in water and the solution allowed to fall into concentrated hydrochloric acid, in which the purpureo-chloride is insoluble, when the small red crystals of the pure salt were precipitated. The first aqueous washings of the product of the reaction were always yellow and yielded a yellow crystalline precipitate of the luteo-nitrate upon the addition of concentrated nitric acid. Hence the product of the action of liquid ammonia upon anhydrous chromic chloride would appear to consist of both purpureo- and luteo-chromic chloride, the latter, however, in smaller quantity than the former. The reaction between anhydrous ammonia and chromic chloride occurs only between comparatively narrow temperature limits. At the ordinary temperature gaseous ammonia is without action. If the chloride is cooled by a mixture of ice and salt, there is a minute quantity only of purpureo-chloride produced after a considerable length of time. Even when a freezing mixture of crystallised calcium chloride and ice is employed, the amount of interaction is but insignificant. It is only in the neighbourhood of the boiling-point of ammonia ($-38°\cdot5$) that the vigorous reaction above referred to occurs, and the action practically ceases immediately above and below this point.

PROF. CHRISTENSEN has made the further interesting observation that anhydrous ferric chloride, $FeCl_3$, likewise reacts with liquefied ammonia. The reaction occurs the moment the liquid touches the chloride, even when surrounded by a freezing mixture of solid carbon dioxide and ether. The product of the reaction is an orange compound probably consisting of an ammoniacal compound analogous to purpureo-chromic chloride. It is, however, more unstable than the latter compound, rapidly evolving ammonia at the ordinary temperature, and it is completely decomposed by water, even the moisture of the air rapidly converting it into a mixture of ferric oxide and sal-ammoniac.

NOTES from the Marine Biological Station, Plymouth.—Last week's captures include the Polyclad *Prostheceræus vittatus*, the Crustacea *Idotea linearis*, *Schistomysis spiritus*, *Crangon trispinosus*, *Polybius Henslowii* and *Portunus holsatus*, and the Mollusca *Calyptræa chinensis*, *Polycera Lessonii* and *Galvina Farrani*. In the floating fauna there has been a marked increase in the numbers of the Siphonophore *Muggiæa atlantica*, which has been present in the townettings from time to time for several weeks past. The larvæ of the Polychæte *Chætopterus insignis* have made their first appearance for the year, and numbers of the Dinoflagellate *Peridinium* and of Echinoid *Plutei* have also been taken. The following animals are now breeding :—The Polychæte *Chætopterus insignis*, the Isopod *Idotea linearis*, the Schizopoda *Mysidopsis gibbosa* and *Schistomysis spiritus*, and the Decapod *Crangon trispinosus*.

THE additions to the Zoological Society's Gardens during the past week include a Yaguarundi Cat (*Felis yaguarundi*), a Brazilian Hare (*Lepus brasiliensis*) from Brazil, presented by Mr. J. E. Wolfe, C.M.Z.S. ; a Common Paradoxure (*Paradoxurus typus*) from India, presented by Mrs. Oswald Walmesley ; two Azara's Foxes (*Canis azaræ*), a Crab-eating Raccoon (*Procyon cancrivorus*) from South America, presented by Lord Lilford, F.Z.S. ; two Common Foxes (*Canis vulpes*) British, presented by Mr. Reginald Chandos Pole ; a Red Deer (*Cervus elaphus*, ♀) British, presented by Mr. C. J. H. Tower, F.Z.S. ; a Spotted Eagle (*Aquila clanga*) from India, presented by Lord Lilford, F.Z.S. ; a Golden Eagle (*Aquila chrysaëtus*) from Scotland, presented by Mr. Hugh Cameron Ross ; a European Pond Tortoise (*Emys europoea*), European, presented by Mdlle. Lajeunesse ; four Midwife Toads (*Alytes obstetricans*) from Belgium, presented by Prof. Gustav Gilson ; a Crab-eating Opossum (*Didelphys cancrivorus*) from Tropical America, an Australian Cassowary (*Casuarius australis*) from Australia, an American Tapir (*Tapirus americanus*), an American Jabiru (*Mycteria americana*) from British Guiana, a Wild Cat (*Felis catus*), European, deposited.

OUR ASTRONOMICAL COLUMN.

METEOR SHOWERS.—In the following list of radiant-points of meteor showers, which we owe to Mr. Denning (*Companion to Observatory*, 1893), that dated for August 10 is stated as being the radiant of a most brilliant shower.

1893.	Radiant. α.	Radiant. δ.	Meteors.
	°	°	
August 4	30	+ 36	Swift : streaks
10	45	+ 57	Swift : streaks
16	61	+ 48	Swift : streaks
21	73	+ 41	Swift : streaks
22	291	+ 60	Slow : bright
23	70	+ 50	Swift : streaks
25	5	+ 11	Slow : short

COMET FINLAY, 1893.—The following is the ephemeris for this comet for the ensuing week :—

12h. M.T. Paris.

1893	R.A. app.	Decl. app.
	h. m. s.	° ′ ″
August 3	5 30 9·0	22 37 54·4
4	34 9·4	22 43 18·4
5	38 7·9	22 48 17·3
6	42 4·4	22 52 51·7
7	45 58·9	22 57 2·1
8	49 51·4	23 0 48·9
9	53 41·8	23 4 12·8
10	5 57 30·2	23 7 14·3

RORDAME-QUÉNISSET COMET, 1893.—In *Astronomischen Nachrichten*, No. 3174, several observations of this comet are inserted. Prof. E. Lamp, July 10, describes the comet as 0′·6 diam., brighter in centre, but no proper nucleus. Dr. F. Restenpart for the next day gives the diameter as 4′, the nucleus being of the 5· magnitude with a shining nebulous envelope. Prof. Schen, for the same day (July 11), estimates the diameter as 2′, and says, that by the 12th the brightness had distinctly increased. On the 13th Herr. Archenhold describes the comet as nearly one-half a magnitude dimmer than λ Ursæ Majoris, of an intense blue colour, and a nucleus 1′ in diameter. M. Bigourdan (*Comptes Rendus* for July 17, No. 3) describes the comet (July 16) as a round nebula of 3′·5 diam., with a small stellar nucleus of 2″ to 3″ diam., surrounded by a brilliant nebulosity. This nebulosity had a diameter of about 20″.

EARTH MOVEMENTS.—In the account of the pendulum observations made by Herr E. von Rebeur-Paschwitz, attention was frequently drawn to the fact that in several cases of earth motions or disturbances, the records indicated that sometimes one followed the other in a short space of time, such as two to three hours, a hint being thrown out that these double perturbations originated from one shock. Happening to examine one of the volumes of the "Transactions of the Seismological Society of Japan," Herr Paschwitz was surprised to find that the earthquake at Kumamato, a town on the west coast of the Island of Kiusiu (lat. 32°·8, long. E. 130°·7), which occurred on July 28, 1889, was the severest that had taken place in Japan in that year, and its time of occurrence coincided with the double perturbation that was recorded at Potsdam and Wilhelmshaven (*Astronomischen Nachrichten*, No. 3174.) Deducing the most probable times for the arrival of the chief disturbance at a mean place (long. 10°·61 E., lat. + 52°·97) he obtained the hours, 3·47h. and 6·10h. M.T. Greenwich. From this point the distance of Kumamato, reckoning on a great circle, is about 8860 kilometres, the complement of this great circle amounting to 31,140 kilometres. Taking into consideration the difference of time of 9h. 19·3m., and that the earthquake occurred at 3h. 28·2m. M. Greenwich time, he deduced the time difference of 67·5m. and 225·3m., or velocities of movement of the wave, as 2·188 and 2·304 kilometres, or about 2·3, taking into account the time inaccuracies. This value was obtained approximately also from the Japan earthquake of April 18 of the same year, the distance being 9000km., the time-difference 64·3m., the velocity of propagation resulting 2·334km.

OBSERVATIONS MADE DURING THE ECLIPSE OF APRIL, 1893.—In the *Memorie della Società degli Spettroscopisti Italiani* for June, 1893, several communications are made concerning observations made at the time of the last solar eclipse. Lona at Palermo, Eugenio, Garibaldi, and Tacchini all give their time observations, while Fenyi, in addition to these, gives a list of the prominences observed at a height of at least 30″ at the epoch of the total eclipse at Chili and Brazil. The following is the list referred to :—

M.T. Greenwich.	Position. N. by E.	Latitude. Mean heliographic.	Height.
h. m.	° ′ ° ′	°	″
0 55	201 4–169 30	−59 W.	103
1 12	130 50–124 32	−64 E.	54
25	75 48– 73 34	−11 E.	33
27	60 6– 53 16	+ 9 E.	51
31	33 24– 28 30	+33 E.	44
—	295 24–294 26	+51 W.	54
—	292	+48 W.	59
—	287 8–286 30	+42 W.	41
1 47	233 48–229 22	−13 W.	34

Father Fenyi gives also a very exhaustive table, or rather diagram, of all the minor disturbances at this time, showing how they were situated with respect to the axis of the sun at the time of the eclipse.

THE OBSERVATORY OF YALE UNIVERSITY.—Dr. Elkin reports as follows to the Board of Managers of the Observatory of Yale University :—"The work with the heliometer has been carried forward during the past year in the directions outlined in my last report. We have examined so far fifty-one stars of large proper motion making in general three sets of measures at each parallax maximum. We have not, however, been able to keep the reductions quite up to date, so that I cannot at this moment give any definite results of our search for large parallaxes. I have also continued the series of parallax measures on the first magnitude stars—Aldebaran, Procyon, Regulus, Arcturus, and Vega having been followed up this year. Dr. Chase has continued the work on Algol, and has commenced a series on β Cygni to test the large parallax deduced by Mr. Jacoby from the Rutherfurd photographic plates. He has also been engaged upon and nearly completed the reduction of his measurements in Coma Berenices. Miss Palmer has been mainly occupied with the computations of our series on Jupiter's satellites, a work of considerable extent." The record is one which Dr. Elkin must regard with the satisfaction that comes to all who make a good use of time.

ASTRONOMISCHEN GESELLSCHAFT.—The following are the articles contributed to the first and second parts of the *Vierteljahrschrift der Astronomischen Gesellschaft* for 1893 :—H. Gyldén, "Untersuchungen über die Convergenz der Reihen welche zur Darstellung der Co-ordinaten der Planeten angewendet werden," and "Nouvelles recherches sur les séries employé dans les Théories des planètes;" E. Anding, Lambert's Photometrie, "Photometria sive de mensura et gradibus luminis, colorum et umbræ; Robert Grant, Second Glasgow Catalogue of 2156 Stars for the Epoch 1890; J. G. Porter, a Catalogue of 1340 Proper Motion Stars; and Charles Pritchard, Researches in Stellar Parallax by the Aid of Photography. There is a list also of all the planet discoveries and comet appearances of the year 1892.

GEOGRAPHICAL NOTES.

DR. H. R. MILL has recently made a systematic bathymetrical survey of the larger lakes of Cumberland and Lancashire, the cost being defrayed by a grant from the council of the Royal Geographical Society. The soundings designed to delineate the general configuration of the various lake basins, were made at close intervals along a series of lines crossing the lake at right angles to its axis, and never more than half a mile apart. These tranverse sections were connected by oblique sections, along which the soundings were more widely spaced, and in addition longitudinal sections were made whenever it was practicable to do so. In Derwentwater the greatest depth found was 72 feet, but the surface of the lake was much below its usual level, being lower, probably, than has ever previously been recorded. Bassenthwaite Lake, though simpler in configuration, was found to have about the same maximum depth. Ullswater, the largest lake in England except Windermere, was found to have a depth of 208 feet, but it is quite possible that deeper soundings might be obtained. This lake was remarkably interesting on account of its division into a series of deep basins separated from each other by wide bars, from the most pronounced of which a rocky islet rises showing the characteristic marks of ice-erosion very clearly. Coniston Lake is simpler, being one practically straight deep trough, the deepest part of which is at least 184 feet below the surface. Wastwater was similar in configuration, though of much greater depth, an area one mile long and a quarter of a mile wide being deeper than 250 feet. The flatness of the floor of this depression may be judged by the fact that 258 feet was the greatest depth found in it. Samples of the deposit from different parts of each lake were secured, and will be examined by a specialist. Temperature observations were also made. It is probable that a similar survey of Windermere will be undertaken in the beginning of September.

MR. F. G. JACKSON sailed last week with a complete equipment for Nova Zembla, where he intends to spend next winter alone, exploring the island and thus gaining practical experience to aid him in his ultimate attempt to reach the North Pole by Franz Josef Land.

THE Paris Geographical Society promotes the study of geography amongst its members by conversational meetings for the discussion of various geographical problems. There are three groups of subjects: (1) mathematical and physical geography; (2) ethnography, anthropology, and the geographical distribution of plants and animals; and (3) historical and economic geography. Those willing to read papers or take part in the discussions at any group enter their names, and are notified of the meetings of their particular section by the general secretary. The importance of this method of promoting an active interest in geography is very considerable, and might well be introduced in this country, where the advantages of informal discussion are rarely recognised.

THE authorities of Owen's College, Manchester, have decided that Mr. Yule Oldham may continue his duties there concurrently with those of the lectureship of geography at Cambridge University to which he was recently appointed.

CELEBRATION OF THE ROTHAMSTED JUBILEE.

THE weather fortunately permitted the celebration on July 29 to take place, as originally intended, in the open air. The lawn in front of the laboratory was filled by the subscribers to the jubilee fund, while, on the common adjoining, a large crowd of spectators was assembled.

The memorial erected in front of the laboratory consists of a natural boulder of Shap granite, weighing nearly eight tons, standing on a rough granite base. On one side of the boulder a part of the surface has been dressed and polished, and bears the following inscription :—

To commemorate
the completion of
Fifty years
of continuous experiments
(the first of their kind)
in Agriculture
conducted at
Rothamsted
by
Sir John Bennet Lawes
and
Joseph Henry Gilbert
A.D. MDCCCXCIII.

The chair was taken by the Right Hon. Herbert Gardner, M.P., Minister of Agriculture, at 3 p.m.

The Secretary of the Jubilee Committee, Mr. Ernest Clarke, then read a list of names of persons who had sent letters or telegrams regretting their absence on the occasion. The list was a long one, and included H.R.H. the Prince of Wales, H.R.H. Prince Christian, the Marquis of Salisbury, Lord Kelvin, Mr. Chaplin, Sir G. Stokes, Prof. Huxley, L. Pasteur, P. Dehérain, E. Tisserand, E. Wolff, F. Nobbe, the Association of Agricultural Colleges and Experiment Stations in the United States, and many others.

The Chairman said they had met to do honour, as far as lay in their power, in the name of agriculture and of the agricultural classes, to two distinguished men, who had rendered invaluable services to our great national industry, and to dedicate that day an outward and enduring memorial of the admiration which the agricultural world felt for the work which they had accomplished. Nothing could be more appropriate for such a purpose than the massive granite boulder which they saw before them. It had already witnessed many of the experiments of nature; they hoped it might stand for many generations to come, as an outward and visible sign of the manner in which the life-long work of Lawes and Gilbert had been appreciated by the men of their time.

He believed, although Sir John Lawes commenced the work of his life as far back as about 1834, it was only in 1843 that the actual field experiments, on which our reliable records were founded, were begun, and in which he was joined by Dr. Gilbert, who had since been the partner of the labours of his life; they were, therefore, commemorating the jubilee of both gentlemen. It must be interesting to all at such a moment to recall the varied succession of agricultural prosperity and depression those two had seen during the past fifty years. During that period their friends had seen wheat rise as far as 78*s*. He thought that was in 1855; and, he regretted to say, since he had had the honour to be President of the Board of Agriculture, it had fallen as low as 24*s*. 8*d*. in May last, making a difference of 50*s*. per quarter. In a meeting like the present, so interested in agricultural subjects, he might say that he thought the development of steam ocean traffic had done more than Free Trade to bring down the price of wheat. There was one ray of hope—he admitted it was a very small one—with regard to the present low and phenomenal prices of wheat. There seemed little doubt, from a calculation he had made, that the extremely low prices were partly due to the extraordinary reserves of that article they had in the country since this 1891. The normal reserve of wheat in this country was calculated to be about 2,000,000 quarters, but since 1891 that reserve, following upon the scare of Russian famine, rose at a bound to over 6,000,000 quarters. At the present moment it had fallen again by something like 2,000,000, and as there was every reason to expect there would not be the same influx of wheat into our country in the present year as there had been in the past, it was possible, when the reserve reached the normal standard again that prices might recover.

A memorial more enduring than the granite boulder before them was furnished by the published records of the experiments. It would always be a pleasant recollection to him to know that since he had occupied his present position he had been able to place some fifty memorials of Sir John Lawes and Dr. Gilbert over the country amongst agricultural institusions—he alluded to copies of their works, which, with the sanction of the Treasury, he had been able to purchase at the public expense.

Mr. Gardner, in conclusion, said it was with the sincerest pleasure and profoundest respect he expressed to Sir John Lawes and Dr. Gilbert, in the names of the agriculturists of this country, their felicitations on their jubilee, and their hopes that they might long enjoy the honour and admiration of all classes of their fellow-countrymen.

The Duke of Westminster said he owed the agreeable position he occupied on that occasion to the fact that he was the ex-President of the Royal Agricultural Society of England, and that during his year of office he had been chosen President of the Rothamsted Jubilee Fund. He had the pleasure of asking Sir John Lawes to accept his own portrait, painted by Mr. Herkomer, and he hoped Lady Lawes, their children, and grandchildren would consider it worthy alike of the subject which it represented and of the old walls which it was destined to adorn. He had further to present both to Sir John and to Dr. Gilbert an illuminated address, signed on behalf of the subscribers by the Prince of Wales, and couched in the following terms .—

"TO SIR JOHN BENNET LAWES, BART., D.C.L., LL.D., F.R.S., &c.

"On behalf of the Committee of the Rothamsted Jubilee Fund and of the numerous subscribers to that fund in all parts of the world, I offer you the most hearty congratulations on the completion of half a century's uninterrupted investigation of agricultural problems of the highest practical value and interest."

"These investigations, which originated with you, relate not only to the growth of cereal and other crops under the most varying conditions, but also to the economic effect of different foods on the development of the animals of the farm. They have embraced, moreover, most important researches concerning the chemical constituents of soils, the rainfall, drainage waters, and the sources from which plants derive their supply of nitrogen."

"During the whole of this period of fifty years you have had the zealous co-operation of your lifelong friend Dr. Joseph Henry Gilbert, whose name will ever be associated with yours, and whom jointly with you we desire on the present occasion to congratulate."

"For the continuance of the experiments and investigations which have already extended over so long a period, you have munificently provided by the establishment of the Lawes Agricultural Trust, so that our successors will profit even more, if possible, than we of the present day have done by your enlightened labours."

"The Memorial which is now erected will, it is hoped, preserve your joint names in honoured remembrance for centuries to come, while the portrait that is presented to you herewith will hand down to future generations the likeness of one of the most disinterested as well as the most scientific of our public benefactors." "ALBERT EDWARD P."

"July 29, 1893."

"TO JOSEPH HENRY GILBERT, M.A., PH.D., LL.D., F.R.S., &c.

"In celebrating the Jubilee of the Rothamsted Agricultural Experiments, it is impossible to dissociate your name from that of Sir John Lawes, and on behalf of the subscribers to the Rothamsted Jubilee Fund in all parts of the world I offer you the most hearty congratulations on the completion of your fifty years of continuous labours in the cause of agricultural science."

"The nature and importance of those labours are so well known that it is needless to dilate upon them; but if the institution of the various investigations and experiments carried out at Rothamsted has been due to Sir John Lawes, their ultimate success has been in a great measure secured by your scientific skill and unremitting industry. Moreover, by your lectures and writings, you have been a leading exponent in this and other countries of the theoretical and practical aspects of the researches that have been undertaken at Rothamsted."

"A collaboration such as yours with Sir John Lawes, already extending over a period of upwards of fifty years, is unexampled in the annals of science. I venture to hope for an extended prolongation of these joint labours, and trust that the names of Lawes and Gilbert, which for so many years have been almost inseparable, may survive in happy conjunction for centuries to come."

"July 29, 1893." "ALBERT EDWARD P."

Continuing, the Duke said it was also his pleasing duty to ask Dr. Gilbert to accept, on behalf of the subscribers, the handsome silver plate which was before them, and which bore the inscription—"Presented by the subscribers to the Rothamsted Jubilee Fund to Dr. Joseph Henry Gilbert, F.R.S., in commemoration of the completion of 50 years of unremitting labour in the cause of agricultural science, 29 July, 1893."

M. Johannet then read an address from the Société des Agriculteurs de France, and M. Aubin, from the same Institution, followed with a congratulatory speech delivered in French.

The Duke of Devonshire, President of the Royal Agricultural Society, said they had not come there to make speeches, but to do honour to the benefactors of their country. He appeared that afternoon, in the name of the 11,000 members of their great Society, to present to Messrs. Lawes and Gilbert the illuminated addresses which were upon the table, and to offer them their most hearty congratulations on the completion of half a century's investigations at Rothamsted. The Rothamsted experiments were a model of what all experimental inquiries ought to be; they had stimulated the carrying out on a lesser scale of other experiments, as those at Woburn and those of numerous local societies. "Practice with Science" was the motto of their Society; it might well be applied to Rothamsted work, which had shed light on many of the vexed questions of practical agriculture. For forty-five years the Society had had the advantage of the personal advice and assistance of Sir John Lawes as a member of its council, and it was proud to recognise in Dr. Gilbert one of the most distinguished of its honorary members. Their contributions to the Society's *Journal* from 1847 to the present time constituted the most valuable series of papers which had appeared in its pages, and they alone would have made the *Journal* famous. For this and all the Society offered to Sir John Lawes and Dr. Gilbert their hearty thanks, hoping that they might long be spared to continue their labours, which, in the words of the Society's charter, were for "the general advancement of agriculture."

Prof. Michael Foster, as senior secretary of the Royal Society, presented two addresses from the Society, and with their hearty congratulations, expressed the hope that the Rothamsted Station might be as fruitful of scientific results in the future as in the past.

Dr. H. E. Armstrong, the President of the Chemical Society, presented an address from that body. He remarked that Rothamsted work was appreciated by none more than by the Fellows of the Chemical Society.

Prof. Stewart, the President of the Linnean Society, presented an address on behalf of the Society. They regarded the Rothamsted experiments as the highest contribution that had ever been made to the science of agriculture.

Prof. E. Kinch presented an address from the Royal Agricultural College, Cirencester. He alluded to the great educational value of the Rothamsted experiments, to the kind reception of the students at their annual visit to the Station, and to the debt of gratitude they owed to Dr. Gilbert for his services as honorary professor at the College.

Mr. Ernest Clarke, in the absence of M. Tisserand, then read an address from the Société National d'Agriculture de France. Mr. Clarke mentioned that several other addresses were on their way to this country.

Sir John Lawes, who, on rising to reply, was received with hearty cheering, said that it was only a very few months since he and his wife received the congratulations of many friends on having attained fifty years of married life, which was occasionally called a golden wedding. That afternoon he had to return thanks to that distinguished company for congratulating himself and Dr. Gilbert on the work they had carried on together for fifty years. When two persons were joined together in marriage they could not part—they were bound together by a solemn tie. Dr. Gilbert and himself were bound by no ties. During the whole of the fifty years Dr. Gilbert had been perfectly at liberty to leave him, and he to leave Dr. Gilbert; they had remained together from their mutual love of the work they had undertaken. He had given to this work all the time that he could spare consistently with other duties; but Dr. Gilbert had given his whole time to it, and had it not been for the labours of Dr. Gilbert, the affairs of Rothamsted would have been in a different state to that in which they now were. Dr. Gilbert had given his life to the experiments—had given the most arduous part of his life—had given his holidays, and this very year he was going to Chicago to deliver a course of lectures on the work at Rothamsted.

He had now had sixty years' experience of agriculture. When he began farming in 1834 the country was suffering from agricultural depression, the crops were so large that they more than supplied the wants of the nation; now our wheat crop only sufficed for one-third of our consumption, and the rest had to be furnished by other countries. He was afraid that their investigations had been of more use to the foreigner than to the English farmer, for the latter had always grown good crops, and thus could not meet lower prices by an increased production, while the foreigner had been able to do this.

Sir John Lawes expressed his cordial thanks for the various presentations made to him that day, and especially for the granite boulder, which he playfully said would probably still be in existence when the portrait had been transferred from the drawing-room to the bedroom, and from the bedroom to the garret, and people had forgotten whom it represented, and who painted it.

Dr. Gilbert expressed himself as unable to return thanks adequately for the ovation of that day. Referring to the early years of their investigations, he said that they commenced with orthodox views; but that, as they could not alter the laws of nature, they presently found that they were at variance with received opinion, and their scientific friends looked on them with pity. Their first paper was subjected to merciless excision by the editor of the journal to which it was sent, and they with difficulty secured its publication. Those who opposed became, however, finally their firm friends, and they had since published in that very journal papers occupying about 2,000 pages. The reason they had been able to steer clear of error in their numerous experimental inquiries at Rothamsted was that they had adhered resolutely to the motto of the Royal Agricultural Society, and had associated practice with science throughout the whole course of their researches. Agriculture, more perhaps than any other art or industry, was dependent upon the intelligent application not of one but of many branches of science, and hence it was that the experimental agriculturist found himself in contact at one time with the botanist, at another time with the physiologist, and again with the chemist and the geologist, the statistician and the economist. He mentioned that he had in preparation a jubilee edition of the memorandum sheet on the Rothamsted experiments, and concluded by expressing his warmest thanks for the sympathetic kindness which his friends had shown him that day.

Sir Joseph Hooker, in proposing a vote of thanks to the executive committee of the Jubilee Fund, said that he had never seen chemistry and botany united to such good purpose as in the investigations of Lawes and Gilbert.

Sir John Evans, treasurer of the fund, in responding, said that the boulder of Shap granite which they saw before them weighed nearly eight tons, and had twice broken down on its way to Harpenden. He need hardly say that a considerable weight had been taken off his mind when he at last had the satisfaction of seeing the huge monolith firmly planted in the place it now occupied.

The Earl of Clarendon proposed a hearty vote of thanks to the Chairman, which was carried by acclamation, and the formal proceedings terminated.

The portrait of Sir John Lawes, by Hubert Herkomer, R.A., was afterwards on view in the laboratory.

A garden party at Rothamsted was held later in the afternoon, which was attended by most of the visitors.

THE GEOLOGISTS' ASSOCIATION IN IRELAND.

THE visit of the Geologists' Association to the counties of Dublin and Wicklow, under the direction of Profs. Sollas and Cole, extended officially from July 24 to July 29; but a number of members arrived in Dublin for Sunday, July 23, and visited the cathedrals and places of historic interest in the city, under the guidance of Rev. Denis Murphy, S.J. On Monday the full party examined the grits and *Oldhamia*-slates of Bray Head. The Rev. Dr. Haughton, F.R.S., delivered a speech of welcome, standing on the rocks of the headland, and Prof. O'Reilly and Prof. Sollas, F.R.S., explained the structure of the mass, showing how the more resisting grits have caused a wrinkled flow of the shales and slates between them. The excursion was continued to the fine intrusive junction of the Leinster granite and the Ordovician rocks at Killiney, the latter being metamorphosed into mica-schists with abundant andalusites and some garnets.

On Tuesday, July 25, the promontory of Portrane was visited, under the direction of Prof. Grenville Cole. The basal carboniferous conglomerates ("Old Red Sandstone") were seen above the Bala series, which is here finely fossiliferous. The igneous rocks, ashes, agglomerates, and some lavas, associated with the great volcano of Lambay, are well seen upon this coast, and a true conglomerate of volcanic blocks and of pebbles, worn from the contemporaneous coral-reefs is one of the most interesting exposures. The brecciation, under pressure, of the alternating layers of shale and limestone produces, near the Priest's Cave, a rock resembling a coarse conglomerate of limestone-pebbles in a matrix of black clay.

On Wednesday, Howth was visited; Prof. Sollas conducted the party, and Dr. V. Ball, Mr. G. H. Kinahan, and Mr. A. B. Wynne were also present. The glacial drift on striated surfaces of Carboniferous Limestone, the dolomitisation of the limestone, the Ordovician dykes of diabase in the quartzites, and the quartzites, grits, and many-coloured shales, of the Howth and Bray series, were studied along the southern shore. Casts of worm-burrows were pointed out in some of the sandstones near the Needles.

On Thursday, July 27, an early start was made for Rathdrum, and cars were taken to Glendalough and the Seven Churches. Prof. Sollas and Prof. Cole led the party to the high ridge above the upper lake to examine the amphibolite in the Ordovician slates. Prof. Sollas showed how the slates had been converted into schists by contact with the Leinster granite, and how pressure has produced a foliated structure even in the intrusive mass; but the amphibolite has converted the schists locally into a "Desmosite," consisting of quartz, garnet, and dark mica, the latter lying in planes across those of the first foliation.

On Friday the Rev. Maxwell Close acted as guide to the shell-bearing sands and gravels, 1,000 feet up on the slope of Two-rock Mountain, near the house called Ballyedmondduff. Small fragments of marine shells were freely found in the upper pit. The party then descended into Glencullen, where Prof. Cole pointed out how the valley had been at one time choked with "drift," full of striated blocks of limestone and *débris* of granite and Ordovician rocks, and how the river has now cut down into this mass, as is the case in so many valleys of the southern and eastern Alps. From Enniskerry the geologists drove through the Scalp, a bold notch in the granite ridge, with an exposure of the junction with contorted Ordovician rocks.

On Saturday a joint excursion was carried out with the Dublin Naturalists' Field Club; some members of the Belfast Field Club being also present by invitation. The whole party drove from Bray up Ben Cree to Loughs Bray, the Rev. Maxwell Close explaining the glacial dam that separates the two lakes, and the moraines in the mountain-hollows round them. The descent was made by the romantic grounds of Luggela, which were kindly thrown open by Mr. Stepney. Here the granite abuts on the metamorphosed Ordovicians, and displays, on Lough Tay itself, a fissile foliated structure of unusual delicacy. On climbing out of the deep hollow to the main road, abundant large erratics of granite, resting on Ordovician schist, were seen on all the moorland slopes.

On Sunday, July 30, Dr. V. Ball, F.R.S., conducted the party over the geological and antiquarian collections in the Museum of the Science and Art Department, Dublin, Major M'Eniry pointing out the treasures of the Royal Irish Academy collection.

THE DEVELOPMENT OF ECHINOCYAMUS PUSILLUS.[1]

THE year 1891 will remain memorable to echinologists for the richness of its products upon the morphology of the class with which they deal, not the least brilliant and far-reaching of which is the discovery by Brooks and Field of the primary bilateral symmetry of the water-vascular system of *Asterias*; but the following year will not pale beside it, if only on account of the magnificent treatise to which we now call attention. The amount of solid work which the author has compressed into his fifty-seven pages is little short of astonishing. The monograph is written in excellent English, and illustrated by nine plates well worthy of the text; and from whatever standpoint it is judged, a verdict of unstinted praise must be given.

After a short introduction, the author furnishes an account of his methods, incidentally alluding to a remarkable result obtained by fertilising ova derived from females reared in a dirty locality with spermatozoa obtained from males dredged in the open sea; and he next proceeds to the detailed consideration of the sexual elements and fertilisation, in the course of which evidence pointing to a possible chemiotaxis is adduced, in what is termed the "attractive forces" of the ova and spermatozoa. The segmentation of the oosperm is next considered. The author remarks that he has more than once seen very delicate connective filaments crossing the cleavage-cavity from one segment to another at the earliest stages in the formation of the former; and later on, in dealing with the phenomena of mesenchyme formation, he calls attention to the significant fact that in young gastrulæ it is common to find mesenchyme cells "attached by one pseudopodium to the ectoderm, and by another to the archenteron," giving the impression "that they facilitate the process of invagination." Interesting as are these facts in their bearing upon the general question of protoplasmic continuity in the animal body, they fall into insignificance beside that portion of the work which deals with the vital phenomena of segmentation itself. In the course of it the author remarks that when studying the phenomena alluded to "one gets the impression that the segments alternately attract and repel each other, and that the highest degree of attraction occurs when the nuclei after a completed segmentation have obtained their rounded distinct form and are in a state of repose." This conclusion is reached after extensive and careful observation, and the tendency of current research in cytology appears to us to suggest that the near future may show the author to have herein formulated a general law.

Dealing next with the blastula and gastrula stages, an apical disc bearing a tuft of long cilia, akin to that of the annelid larva, is described; and the author, having proved that it has nothing to do with locomotion, provisionally suggests that it may be a larval sensory organ. The formation of calcareous deposits is recorded to first occur during the blastula stage, and the spines, interradial plates, and spherids of the young urchin, are alike traced to a "first indication" in the form of a minute tetrahedron originated by the agency of mesenchyme cells; and the author, after full consideration, inclines to the belief the "teeth" also "originate as small tetrahedrons." The detailed observations incorporated in this section of the work are of intense interest, especially in their bearing upon the attempt of Dreyer to reduce the skeletogenesis of the echinodermata and certain other invertebrated animals to a common principle of purely mechanical origin.

The young urchin is traced to a "first indication" in an ectodermic invagination of the Pluteus, as previously described by Agassiz and Mentschnikoff, and the author observes that the disc-like sac thus formed becomes differentiated into a "thick-walled bottom," which plays an important part in the development of the young urchin, and a remaining portion which "only serves as a kind of amnion."

One very curious and interesting discovery which is announced is that of a choano-flagellated condition of the cells of the ciliated band of the Pluteus, which, in the author's words, "curiously remind one of collar-cells in the Porifera;" and it is not a little remarkable that this observation should have been closely followed by that of Franzé that Bütschli's so-called "*mund vacuole*" of the Choano-flagellate Infusoria (*Codosiga botrytis*) is in reality a delicate membrane connecting the collar with a specialised sucking vacuole.

In his introduction the author confirms the surmise of Johannes Müller that certain of his (now classical) descriptions of Echinoid larvæ were those of *Echinocyamus pusillus*, and in so doing points out that nobody has in the meantime published anything on the development of that animal. Our appreciation of the excellence and value of the author's work may, perhaps, be best expressed in the assertion that it appears to us in every way worthy of this unique association with that of the great founder of our modern comparative anatomy.

[1] A Monograph, by Prof. Hjalmar Théel, Nova Acta Reg. Soc. Sci. (Upsala: Ser. iii. pp. 1-57. 1892.)

FRANCE AND INTERNATIONAL TIME.

THREE years ago M. W. de Nordling made a communication to the French Geographical Society with regard to a universal hour. In a further communication to the same society, on April 7, he traces the changes that have been made since 1889. The state of things at the present time are summarised as follows:—

(1) The time of eastern Europe, which differs by only one minute from that of St. Petersburg, is employed in Russia, Roumania, Bulgaria, and Roumelia, to Constantinople.

(2) The time of Central Europe prevails in Sweden, Germany, Austria, Hungary, Bosnia, Servia; and its adoption is assured in Switzerland, Italy, and Denmark.

(3) The time of Western Europe (Greenwich time) is in use in Great Britain, Holland, and Belgium, and, to complete its European domain, needs the addition of France, Spain, Portugal, and Ireland.

With regard to France, M. de Nordling dwelt on the fact that while civil time is referred to the Paris meridian, the railway service runs according to Rouen time, which is five minutes behind Paris time. The French Commission of 1891 remarked upon the absurdity of this system in the following words:—

"In order that there should be no ambiguity in the use of the uniform hour adopted, it will be necessary to put an end to the curious habit that exists only in France, where two timepieces are seen at all railway stations having between them a constant difference of five minutes.

"It is useless for the railway companies to say that the interior time of their stations concern them particularly, and only refer to their service; only error and confusion can result from the system. The hours of departure being regulated by the interior clock, there must always be a tendency to consider these indications as the most exact.

"To our knowledge, in no other country outside our own, is this peculiarity found, which perpetuates an error, and, in fact, puts the trains behind by five minutes."

"It is said," remarked M. de Nordling, "that the five minutes retardation are regarded with approval by travellers.

"This was probably true in 1840, when one would only go to Saint-Germain and Versailles, but to-day, when everybody discounts the five minutes, they have lost their virtue, and only force the passenger to make incessant calculations. The uncertainty is increased in the buffets, where it is doubtful whether the clock on the wall indicates interior or exterior time.

"It is not only from a national point of view that this dual hour is vexatious, but also from an international point of view. In fact, it renders our hour absolutely inappropriate to all international usage. Suppose Switzerland had adopted Paris time;

its railways would not be less in discord than our own, ruled by Rouen time, and the principal object of the pretended unification would be lost. At the present time, it is true, this consideration is only retrospective, since it is evident to those who have eyes to see, that in the future any international horary amalgamation will be based on the united times of all meridians.

"What sacrifices would a similar amalgamation impose on France? In the first place, it would retard the clocks of our railways by four minutes, and civil time by nine minutes. But, from the experience furnished by the law of March 15, 1891, it can be affirmed that—were it not for the difference between interior and exterior timepieces of the stations—the reform would pass absolutely unperceived by the public.

"It can no longer be said that the change implies a question of national self-respect, since it is not to adopt English or German time, but to take up a universal system already adopted by the greater part of Europe, by all North America, and by a part of Asia (Japan).

"It is true that the new system will be imperfect so long as France will not adhere to it. It is not only by the adherence of France, however, that this system will be crowned. If France wants to justify the provisions of the 1891 Commissioner of the Senate, it will delay the execution for a hundred years. But we do not delude ourselves with views of this kind. During the time of waiting, our horary system will produce in the eyes of Europe—in the eyes of the world—the same effect as an old building out of line, encroaching on the public view, breaking the perspective of a beautiful straight avenue, and from which passers-by will only turn with displeasure. Is this a dignified situation for France?

"The situation is made worse from another cause. It has been said that Spain and Portugal are becoming friends again. If, according to the opinion of to-day, these two countries desire to unite their times, it is probable that, in order to avoid a conflict between the meridians of Madrid and Lisbon, they will take the time of Western Europe. If that occurs the isolation of France will be complete.

"There are two ways of escape from this difficulty. The first is based on the question of legality, and is that the Minister of Public Works shall invite our railway companies to retard their clocks by four minutes, and that the Minister of the Interior shall prescribe in his turn that all the public clocks be put back nine minutes with regard to the meridian of Paris. This international unification would have been made had not the law of March 15, 1891, been violated up to now.

"The other way, and the one altogether more frank and dignified, is this—that France should say to Spain, 'Would you be willing to unite our times? Let us adopt, with Portugal, the time of Western Europe, and agree as to the day when it shall be put in force simultaneously.' If France obtains this understanding, it will have done more for the unification of hours than any other nation; for each nation has only acted on its own account, while France, in bringing its adherence, would bring at the same time that of two companions. This would be at once the crowning of the system.

"I guarantee that France would receive the plaudits of the entire world, both of the old and the new, and in this question we should, at the first onset, have resumed the place which we generally occupy at the head of progress."

The editor of the *Revue Scientifique* remarks, in a footnote to M. de Nordling's article, "It is false patriotism that is willing to remain apart from other lands. Are the English who do not wish to adopt the metric system, and the Chinese who built a great wall at their frontier, good patriots? And are these two examples so worthy of admiration that our ambition should be to imitate them by refusing to accept the unification of hours. The conclusion can be formulated in three simple propositions:—

"(1) Adopt a single time for all France, without having the time in the interior of railway stations five minutes behind.

"(2) Adopt the time known as that of Western Europe—that is, Greenwich time, which is nine minutes behind Paris time, and which is in reality the time of central France (Havre, Le Mans, Tours, Poitiers, Angouleme, Auch, and Oran).

"(3) Urge Spain and Portugal to adopt this time."

It is satisfactory to find that the subject of international time is being seriously considered in France. The changes required to refer the times to the Greenwich meridian are so small that, but for national prejudice, they would doubtless have been made long ago. However, we are not in a position to moralise upon the opinions of our neighbours as to the adoption of the time of Western Europe, for they point to our absurd system of weights and measures, and we are humiliated. There is little doubt that the French will adopt Greenwich time before the metric system is introduced into this country.

OLIGODYNAMIC PHENOMENA OF LIVING CELLS.

AMONG the botanical papers left by the late Prof. Carl v. Nägeli is a very remarkable one bearing the above title, which is now published in the *Denkschrift* of the *Schweizerische naturforschende Gesellschaft* by Prof. Schwendener and Prof. Cramer. The observations referred to occupied the closing years of Nägeli's life since 1880.

By oligodynamic phenomena Nägeli means those produced by excessively small quantities of metallic substances in solution. The experiments were made chiefly on two species of Spirogyra, *S. nitida* and *dubia*. If in water which is previously "neutral," *i.e.* not pathogenic to Spirogyra, a gold coin containing ten per cent. of copper is placed, the water acquires the oligodynamic property of killing the alga, and the poisoning may begin to manifest itself in as short a period as from three to six minutes. Nägeli satisfied himself that this effect is not due to the action of electricity or of any similar force, but is the result of infinitesimally small quantities of copper dissolved in the water, in the form of CuH_2O_2 combined with carbon dioxide. In this way one part of copper in 1000 million parts of water may act pathogenically on the alga. Similar results were obtained with silver, zinc, iron, lead, and quicksilver, while the absolutely insoluble metals gold and platinum were without effect. In this way distilled water is often poisonous to Spirogyra, and it is a remarkable fact that the poisonous metals communicate the property to glass vessels in which they are placed. The poisonous properties of the water may be diminished or entirely neutralised by placing in the water particles of some insoluble solid substances, such as sulphur, graphite, cellulose, wood, coal, silk, wool, &c., which present a large surface on which the metal is precipitated. For the same reason, while the alga will be killed if only a few filaments are present in the water, a much larger quantity will be entirely uninjured.

Oligodynamic poisoning manifests itself in the living cell in a different way from true chemical poisoning. In the former case the cell does not at once lose its turgidity; the protoplasmic uricle remains for a time adherent to the cell-wall, while the spiral band of chlorophyll detaches itself and becomes transformed into a solid mass surrounding the rounded nucleus of the cell. The substance of the band swells up, and presents, on transverse section, a cylindrical or oval form. The phenomena present some resemblances to those produced by electricity.

The very remarkable results here described are confirmed by Prof. Cramer, who has repeated the experiments, and finds, in all essential points, the phenomena to resemble those obtained by Nägeli. A. W. B.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

A COURSE in Naval Architecture has been recently established at the Massachusetts Institute of Technology to provide a thorough training in the theory and methods of designing and building ships, together with a study of the properties requisite for safety and good behaviour at sea. It is intended to cover the same ground and accomplish the same results as the English and French government schools for training Naval Constructors. Like all the courses at the Institute it gives, in addition to professional and technical training and equipment, a good scientific and liberal education. Attention is directed mainly to the construction of merchant steamships; but some attention is given to problems arising in the design of men-of-war, which offer at once the most definite and the most intricate questions presented to the naval constructor. The theory of the construction of sailing vessels is also included in the course.

THE *Westminster Budget* of July 28 contains a record of the scholarships obtained by boys at our public schools during the scholastic year 1892-93. Though the record cannot be regarded as the best criterion of efficiency, owing to the fact that many of the scholarships are confined to certain schools, and that their values vary considerably, still an indication is obtained of the attention paid by schools to different subjects. The highest number of science scholarships, four, was obtained by Manchester. Epsom and St. Paul's follow with three each, and then Charterhouse, Dulwich, Shrewsbury, and Tonbridge with two each. In mathematics, Clifton, Tiverton, and Merchant Taylor's each obtained three scholarships. The following schools obtained two: Christ's Hospital, St. Paul's, Bristol, Chester, Leatherhead, Liverpool, Wolverhampton, Liverpool Institute, and Wellingborough.

The vote of £6,200,000 for public education in England and Wales which was agreed to on Monday, is the largest that has ever been requested for that purpose. In his speech on the subject, Mr. Acland referred to the suggestion that the Bethnal Green Museum should be handed over to the London County Council, and said that if the Council should desire to have the site and the building on reasonable conditions for educational purposes, the Government would be glad to meet them in a reasonable way.

Mr. R. W. Stewart, Assistant Lecturer and Demonstrator in Physics in the University College of North Wales, Bangor, has just been granted the degree of Doctor of Science by the University of London. Mr. Stewart's thesis contained the results of a series of experimental determinations of the thermo-conductivities of iron and copper, made in the Physical Laboratory of the University College of North Wales. The results are embodied in a memoir which was recently communicated to the Royal Society by the President (Lord Kelvin), and which has been accepted for publication by the Council of the Society.

The *British Medical Journal* says that several changes have recently taken place in the teaching staff of St. Bartholomew's Medical School. Among them we note that Dr. F. D. Chattaway has been elected to the Demonstratorship of Chemistry; and Mr. Alfred Howard has been appointed to the Assistant Demonstratorship. Mr. J. S. Edkins, at present George Henry Lewis student, and late Senior Demonstrator of Physiology at Owens College, Manchester, has been elected Demonstrator of Physiology.

Mr. D. T. MacDougal has been appointed Instructor in Vegetable Physiology at the University of Minnesota.

SCIENTIFIC SERIALS.

The Quarterly Journal of Microscopical Science, for July, 1893, contains:—On the morphology and physiology of the brain and sense-organs of Limulus, by Dr. W. Patten (Plates 1 to 5). Some two years ago the author published a paper in the *Quarterly Journal of Microscopical Science* calling attention to many striking resemblances between Arachnids and Vertebrates, and maintaining that the latter are descended from a great group of the former, in which he included the Arachnids, Trilobites, and Merostomata. Attention was called to the evidences of relationship as shown in the invaginations which in insects give rise to the optic ganglia, and in scorpions and Limulus become so extensive as to enfold not only the optic ganglia but the eyes and the forebrain as well. A cerebral vesicle is thus formed, from the floor of which arise the forebrain and the optic ganglia, and from the roof a tubular outgrowth, at the end of which lie the inverted retinas of the parietal eye. Such a condition is to be found only in Arachnids and Vertebrates, and the author thinks it affords as trustworthy evidence of relationship as the presence of a notochord or of gill-slits. Other relationships were indicated between the lateral eyes in Limulus and Vertebrates, between the cartilaginous endocranium in Arachnids, and the primordial cranium of Vertebrates, between the subneural rod in scorpions and the notochord, and in the correspondence between the neuromeres and nerves in Arachnids and Vertebrates. To this long array of evidence the author now adds others: identifying nearly all the important lobes and cavities characteristic of the Vertebrate forebrain in the forebrain of Limulus; showing that the coxal sense-organs are gustatory, and correspond to the supra-branchial sense-organs of Vertebrates, and describing a remarkable organ in Limulus, which has all the characteristic morphological features of the olfactory organs in Vertebrates. The author believes that it may now be regarded as beyond any reasonable doubt that the Vertebrates are descended from the Arachnids. The very interesting palæontological aspect of the subject is promised in a separate memoir.—On the structure of the pharyngeal bars of Amphioxus, by Dr. W. Blaxland Benham (Plates 6 and 7), gives a detailed account of the tongue (or secondary) bar in Amphioxus, and institutes a comparison between it and the primary bar, and there is a *résumé* of the observations of recent observers and an account of certain abnormal bars.—On the perivisceral cavity in Ciona, by A. H. L. Newstead, B.A. (Plate 8). The author found (1), that there are no communications between the perivisceral cavity and the atrial cavity (such as were described by Kupffer, though denied by Roule); (2) that definite communications exist between the perivisceral cavity and the pharynx, and as these openings occur in the same position as the orifices described by Kupffer, it is probable that the supposition of van Beneden and Julen is correct, that the orifices observed by Kupffer open into the perivisceral and not into the atrial cavity. The perivisceral cavity is regarded as a specially modified epicardium, which has become greatly enlarged.—On the early stages in the development of *Distichopora violacea*, with a short essay on the fragmentation of the Nucleus, by Dr. Sydney J. Hickson (Plate 9). In this paper we have first an account of the early stages of the development of *Distichopora violacea* from material collected by the author in North Celebes and by Prof. Haddon in Torres Straits; then an account of the formation of the germinal layers in the Cœlenterata. A sketch of the developmental histories, as known up to the present, is given, with the typical invaginate gastrula at one end and the multinucleated plasmodium at the other; and, lastly, the important question of the "fragmentation" of the Oosperm nucleus is very ably and judiciously discussed, the following conclusions from the evidence adduced being drawn: (1) Fragmentation of the nucleus is a normal method of nuclear division, and is not always a sign of pathological change; (2) in many cases where the nucleus is supposed to disappear, there is, as a matter of fact, only a minute fragmentation; (3) that fragmentation only occurs when there is no cell division; and (4) that karyokinetic division of the nuclei is caused by the forces in the cell protoplasm which bring about the division of the cytoplasm. The phenomena of pluripolar mitosis may afford examples of intermediate types.

Bulletin de l'Académie Royale de Belgique, No 5.—On negative hydrostatic pressure (continued), by G. Van der Mensbrugghe. A test-tube is completely filled with water, and another, with thin walls and a little narrower, is plunged into it to about half the depth. On inverting the two tubes the smaller one rises through the water in the other in spite of gravitation, owing to the suction exerted by the water, whose internal pressure is less than that of the atmosphere. If a tube of paper or of waxed silk be substituted for the smaller test-tube, the flexible tube is flattened when plunged down into the other, but regains its circular section on placing the system upside down. Just as it is possible to subject a large vessel to an enormous internal pressure by ordinary hydrostatic pressure, so it is possible, on the other hand, to subject it to a corresponding external pressure by inverting the hydrostatic tube.—Researches on monocarbon derivatives, by Louis Henry (continued). This contains an account of the mono-chloric, mono-bromic, and mono-iodic oxides of methyl.—Contribution to the study of trichinosis, by Dr. Paul Cerfontaine. A study of some cases of the epidemic of Herstal, near Liège, in January, led to the following conclusions. As soon as the infected meat is introduced into the system, the cysts are destroyed, and the larvæ liberated in the stomach, whence they pass after some time into the intestine. There they grow rapidly, and fecundation takes place in the intestine after the second day of infection. The males are then expelled from the system, and many of the females penetrate the walls of the intestine and even enter the mesentery, where they produce offspring after the sixth day of infection. This penetration of the walls of the intestine gives its peculiarly fatal character to trichinosis. The young entozoa are dissiminated throughout the system by the lymphatic vessels, which carry them into the blood. Owing to their small size they penetrate into the capillaries, and produce congestion of the blood-vessels and œdema. Death is often due to what amounts to a maceration of the respiratory muscles, producing asphyxia

Wiedemann's Annalen der Physik und Chemie, No. 7.—On the specific heats of glasses of various compositions, by A. Winkelmann. The specific heats of the various constituents of different glasses were calculated or experimentally determined, and those of the glasses made up of them were calculated by Wöstyn's law, according to which a specific heat of a compound is obtained by adding together the products of the specific heats, the atomic weights, and the number of atoms of the elements contained in the compound, and dividing by the sum of the products of the atomic weights and numbers of atoms. On comparing the values thus calculated with those found by experiment, it was found that they agreed to within one per cent.—On a surface connected with the electric properties of tourmaline; thermodynamics of tourmaline and the mechanical theory of muscular contraction; and molecular theory of piezo-electric and pyro-electric phenomena, by E. Riecke. The author makes the attempt of formulating a thermodynamical theory of muscular contraction, and investigates its connection with the pyroelectric phenomena of tourmaline. He arrives at a formula in which the state of the muscle can be expressed by two variables only, the temperature and the tension.—Concerning the theory of electric oscillations in wires, by A. Elsas. The author shows that the Hertzian oscillations may be completely explained on the older electromagnetic theory, without reference to Maxwell's amplifications. He does not contend that Maxwell's theory is superfluous, but finds out how far the older theory is capable of proceeding without having recourse to Maxwell's conceptions.—Objective representation of Hertz's experiments, and the high tension accumulator, by L. Zehnder. A collection of practical hints for the performance of oscillation experiments by means of the 600-cell Planté accumulator.—Contributions to the theory of secondary batteries, by Franz Streintz. With comparatively low current densities, the resistance during discharge attains a maximum. As the current increases, the resistance slowly falls to a value equal to that in open circuit, and falls still further at higher current strengths.—On the determination of the length of a solenoid, by F. Himstedt. Contrary to Heydweiler's opinion, the length and radius of a solenoid as determined by its electromagnetic effect are not appreciably different from their geometrically calculated values.

IN the *Botanical Gazette* for June Mr. R. H. True has a paper on the development of the caryopsis, which supports the ordinary view respecting the formation of the fruit in grasses. Prof. Atkinson continues his account of the biology of the organism which causes the tubercles on the roots of Leguminosæ.

IN the *Journal of Botany* for July, Mr. A. B. Rendle describes and figures a case of the production of tubers within a tuber in the potato. Yet two more "species" are added to the long list of British *Hieracia* by Messrs. E. F. and W. R. Linton, *H. enstales* and *orcadense*.

IN the *Nuovo Giornale Botanico Italiano* for July is a paper by Sig. E. Baroni on the anomalous genus *Rohdea*, which he prefers to place in the order Liliaceæ and tribe Asparageæ, rather than in the Araceæ. The minute structure of *Rohdea japonica* is described, and the mode of pollination, which appears to be effected partly by insects, but largely by snails, and even by spiders.

THE *Bulletino della Società Botanica Italiana*, Nos. 5–7, are largely occupied by papers chiefly interesting to Italian botanists. In addition, Sig. A. Baldacci has some observations on the sympodial branching in *Symphytum* and in other Borragineæ, and on the mode of branching in the Apocynaceæ, which appears to be also sympodial. Sig. U. Brizi enumerates the fossil Musci and Hepaticæ found in a locality within the Roman territory. Sig. C. Acqua describes the mode of formation of the wall in the growth of the pollen-tube of *Vinca major*, which presents a strong resemblance to that described by Buscalioni in the aerial hairs of *Lavatera*. Sig. C. Massalongo has several papers on galls.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 1.—"On the Colours of Sky Light, Sun Light, Cloud Light and Candle Light." By Captain W. de W. Abney, C.B., D.C.L., F.R.S., P.R.A.S.

The author has made several comparisons of the above lights throughout the different parts of their spectra, and has been able to verify their correctness by means of templates rotating in the spectrum of electric light, as described in Part II., "Colour Photometry," Phil. Trans., 1889. It seemed, however, that it would be useful if the colours of these lights could be expressed in single wave-lengths, together with the amount of added standard white light, the latter being expressed in terms of the luminosity of the dominant colour, in accordance with the method brought before the Royal Society in Proc. Roy. Soc., 1891.

When measuring light from the sky, a beam from the zenith or other desired part was reflected through a blackened tube into a darkened room in which the colour patch apparatus ("Colour Photometry," Abney and Festing, 1886) was placed, and the image of the end of the tube was focussed on to the front surface of a cube, the front surface of which was coated with zinc white, its background being black velvet. The patch of colour from the apparatus was also thrown on the cube. A rod placed in the paths of the two beams enabled the sky light and the spectrum colour to be examined side by side. The slit in the spectrum was an adjustable one so that any intensity of colour within limits would fall on the cube. A beam of white light reflected from the first surface of the first prism was again reflected from the surface of a thin prism on to the cube, a rod placed in its path cast a shadow on that part illuminated by the sky light, and by suitable adjustment the boundaries of the two shadows were caused to exactly coincide. The colour was thus diluted with white light, and rotating sectors, described in other papers, being placed in the path of the white beam, enabled the dilution to be regulated.

Sky Light.—On June 27, 1892, at 2.30 p.m., the sky was a good blue, but not a dark blue, and perhaps rather milky. The slit was moved into the part of the spectrum which appeared to be near the dominant colour. The colour was diluted to approximately the required amount. The slit was shifted and the dilution altered until the two colours made a perfect match. It was found that on the standard scale of the spectrum the dominant colour was represented by 28·6, which is λ 4800. The mean value of the sector aperture was 32°, and recollecting that the sectors are double sectors the comparison has to be made with 180°. The next operation was to compare the luminosity of the whole beam of white light with that of the colour. The sectors still remained in the white; the sky light was cut off, and the rod altered till the colour and the white were alongside each other with the boundaries of the shadows touching. The luminosities of the two were compared, and it was found that the aperture of the sector was 14°. As it required 32° of white to make the dilution of the colour, it follows that 32/14, or 2·286, parts of white were required to dilute 1 part of the blue. This may be expressed thus—

$$\text{Sky light} = \lambda\ 4800 + 2{\cdot}3\text{W}.$$

On July 4, 1892, at mid-day, the same procedure was adopted, and the dominant wave length was again λ 4800. In this case the amount of added white was thus—

$$\text{Sky light} = \lambda\ 4800 + 3{\cdot}1\text{W};$$

in other words, the sky was more milky.

At 4 p.m. on the same day the sky to the east, and about 30° above the horizon, was evidently slightly greener, and it was found that the colour agreed with scale No. 29·6 or λ 4834, and that it required three parts of white to be mixed with it.

$$\text{Sky light} = \lambda\ 4834 + 3\text{W}.$$

On other days, when the light of the portion of the sky near the zone of maximum polarisation the dominant wave-length was found to be between these two limits, and was never found bluer, and the smallest admixture of white light was found to be 1·9.

From these measures it may be concluded that the dominant colour of a blue sky is λ 4800.

Amongst artists it is not uncommon to employ cobalt to render this colour, and in many instances this is mixed with Chinese white.

The dominant colour of cobalt was found to be at scale No. 29, or λ 4812, when illuminated by ordinary day light, whence it seems that, as far as colour is concerned, it is singularly fit for the purpose.

Sun light was compared in the same manner, but the beam was reflected from the surface of a prism into a dark room, and again diminished in intensity by placing in its path rotating sectors with very narrow apertures.

Near mid-day on July 8 the sun was very clear, the sky being free from clouds, and a strongish wind blowing from the west. Two separate sets of measures were made with an interval of an hour between each. It was found that the dominant colour was λ 4885 in both cases, and in the first set it was diluted with 5·45 of white, and in the other with 5·14 of white. This indicates that sun light contains slightly more green-blue rays than the light emitted from the crater of the positive pole of the electric light. This agrees with the spectrum measures made in "Colour Photometry."

Cloud light was next matched on days in which the sky was overcast. A comparison of the general light of the zenith was all that was attempted, and near mid-day.

It was found that it required 1 part of λ 4864 diluted with 5·5 parts of white to make a match. It will be seen that the dominant colour of cloud light lies between that of the sky and of the sun, as might be expected, and is decidedly whiter than the sky, as might also be anticipated.

Various comparisons of sunset colours have been made, and found to range from λ 6300 up to λ 4800; in some cases it was necessary to match by means of complementary colours.

The light from a paraffin candle it was found could be very closely matched with D sodium light. The equation may be expressed as follows :—

$$\text{Candle light} = \lambda\, 5880 + 0{\cdot}4\text{W}.$$

The amount of added white varied from 0·1 to 0·5, and it is in this part of the spectrum that a large number of separate observations are required in order to get a good and fairly trustworthy mean.

June 15.—"Some of the Effects and Chemical Changes of Sugar injected into a Vein." By Vaughan Harley, M.D., Teacher of Chemical Pathology, University College, London, and Grocer Research Scholar. Communicated by George Harley, M.D., F.R.S.

When 10 grams of grape-sugar per kilo. of body-weight of a dog are injected into a vein and elimination by the kidneys prevented, the sugar so rapidly disappears from the circulating blood that it reached the normal quantity within six hours. The quantity of glycogen in the liver and muscles is not markedly increased.

The amount of lactic acid in the blood is increased to so marked a degree as in some cases to be more than the quantity of sugar. The greatest amount of lactic acid is found in the liver. Alcohol, acetose, and aceto-acetic acid are also present in the blood after the introduction of the sugar. There is no increase in the quantity of ammonia in the blood.

The introduction of the sugar causes marked disturbance of the nervous system, shown by the appearance of muscular spasms, hurried breathing, and finally coma. These are probably due to some of the products derived from the breaking down of the sugar molecules acting as a poison, which by further breaking up into other substances become harmless and the animals recover.

"Studies in the Morphology of Spore-producing Members. Part I. Equisetineæ and Lycopodineæ." By F. O. Bower, D.Sc., F.R.S., Regius Professor of Botany in the University of Glasgow.

The first pages are devoted to the discussion of points of general morphology of the sporophyte, as it is seen in archegoniate plants, together with a sketch of the history of opinion as to the morphological "dignity" of the sporangia, and their relation to the parts (usually sporophylls) which bear them. The position of Goebel is adopted, that sporangia are as much organs, *sui generis*, as are shoots, roots, &c., no matter where they may be seated.

It is customary to assume that the ontogeny will serve as a guide to the history of descent in plants as in animals. As applied in detail to the sporophyte generation this assumption cannot be upheld: for the conclusions drawn from wide comparison would be directly antagonistic to such a history. The young sporophyte of a fern first forms foliage leaves, stem, and roots; only after a considerable period are sporangia produced. On the recapitulation theory it would be concluded from this that the vegetative system was the first to appear, while sporangia were of subsequent origin, and it might further be held that sporophylls are metamorphosed foliage leaves. But the whole comparative study of the sporophyte of lower forms leads to the opposite conclusion; spore-production was the first office of the sporophyte, and if the lower Bryophyta really illustrate the mode of origin of the sporophyte, the production of spores preceded the existence of a vegetative system of the sporophyte, and has apparently been a constantly recurring event throughout evolution. It must therefore be concluded that the history of the ontogeny does not truly recapitulate the history of the descent as regards the neutral generation; the sporophyte is, in fact, an intercalated phase which has acquired vegetative characters. Comparative study of the Bryophyta leads to the conclusion that the whole vegetative region was the result of progressive sterilisation of potentially sporogenous tissues.

A brief review of the progress of this sterilisation as it has already been recognised among the Bryophyta is next given; it is pointed out that (*a*) the sterilisation may involve the whole thickness of the sporophyte, as in the formation of the seta, or (*b*) it may make itself apparent only in individual cells of the sporogonial head (elaters). But the Bryophyta are clearly marked from vascular plants by two characters: (1) the absence of appendicular organs; (2) the single continuous archesporium.

There are, at least, three possible ways in which plants with numerous separate archesporia may have originated from plants of some Bryophytic type: (1) by branching (chorisis) of a sporogonial head; (2) by formation of entirely new archesporia, having no direct connection by descent from pre-existent ones; (3) by partitioning of a continuous archesporium.

The frequent presence of synangia in eusporangiate Vascular Cryptogams suggests either coalescence accompanying reduction in a descending series, or partitioning by means of septa in an ascending series; the first question in connection with such synangia will be whether in any natural sequence of Vascular Cryptogams the progression from a non-septate to a septate condition can be traced; or the converse. Though the facts at hand do not amount to an actual demonstration, the Lycopodineæ and their allies are believed to be an ascending series, and they are seen to supply important evidence. *Phylloglossum*, *Lycopodium*, and *Selaginella*, *Lepidodendron*, and the Psilotaceæ show natural affinities. To this series *Isoetes* may be added.

As regards the sporangia, there can be no doubt of the homology of the sporangium of *Phylloglossum*, *Lycopodium*, *Selaginella*, and *Lepidodendron*. Within the genus *Lycopodium* differences of detail have been observed analogous to such differences as would result in the production of more bulky sporangia, such as those of *Lepidodendron* and *Isoetes*, though it is true these differences are not so extensive. In these very large sporangia trabeculæ are found, as rods or plates of sterile tissue, which may project far upwards into the sporangial cavity (*Lepidodendron*), or may extend the whole way through it to the upper wall (*Isoetes*). In the latter case it has been shown by Goebel that the trabeculæ are the result of differentiation of a potential archesporium, part of which is sterilised and forms the trabeculæ.

The next step is to the Psilotaceæ; and the first question is that of the real nature of the synangium in these plants. Sections both of *Psilotum* and *Tmesipteris*, show the synangium to originate below the apex of the sporangiophore, and from its upper surface, in a manner very similar to the sporangium of *Isoetes*. The form of the young synangium resembles that of the sporangium of *Lepidodendron*, with which genus also there is extraordinary anatomical similarity. The septum is similar in its origin to the sporogenous masses, and is not at first distinguishable from them; in this respect it also resembles *Isoetes*. It would thus appear that the whole synangium is comparable in origin and position, in the broad lines of development, and in function to the sporangia of other Lycopods, *that is, a septate comparable with a non-septate body*.

Tmesipteris appears to be a variable plant as regards the form and structure of its synangia; there is, however, some method in its irregularities; smaller synangia of simpler form and structure are found at the limits of its fertile zones, while about the middle of it synangia have been found with three loculi, corresponding to those of *Psilotum*. Examination of those of simpler form shows *that they may be only partially septate, or the septum may be absent from the first*. I have been able to prove in young synangia of this type that *the tissue which would normally form the septum may be sporogenous*; this is exactly the converse of what has been proved by Goebel in *Isoetes*, and the conclusion which may be drawn is that *there is no essential difference between the tissue which will form septum or trabeculæ and that which will form spores, since they can mutually undergo conversion.*

It has already been shown by others that in *Psilotum* the number of loculi in the synangium may vary, being sometimes two, normally three, but occasionally four or five. In *Tmesipteris* it may be one, two, or three; and as there is no doubt of the homology of these within the Psilotaceæ, we may conclude *that in homologous parts the loculi may vary in number from one upwards.*

We may recognise within the species *Tmesipteris* a correlation of size to number of loculi; the smallest specimens have no septum, and these are produced at the limits of the fertile zone, where nutrition may be failing; those which are of normal size have two loculi: occasionally, when of large size and well nourished, as at the middle of the fertile zone, the loculi may be three. Here is illustrated in one species much the same sequence as is seen elsewhere for distinct genera, such as *Lycopodium*, *Isoetes*, *Lepidodendron*: where the sporangium is small there are neither trabeculæ nor septa, the exigencies of nutrition, and perhaps also of mechanical strengthening, not being felt (*Lycopodium*): where the sporangium is large sterile bands of tissue are present; these appear as trabeculæ or incomplete septa *Lepidodendron* or *Isoetes*, but as complete septa in the large synangia of *Tmesipteris*. To those who accept the homology of the synangium of *Tmesipteris* with the sporangium of other Lycopodinæ the probability of this will appear specially strong. Such facts as these and their theoretical bearing are discussed at length in the memoir: the opinion is finally expressed that progressive sterilisation and formation of septa are factors which will have to be taken into account in solving the problems of origin of vascular plants.

"Magnetic Qualities of Iron," by J. A. Ewing, M.A., F.R.S., Professor of Mechanism and Applied Mechanics in the University of Cambridge, and Miss Helen G. Klaassen, Lecturer in Physics, Newnham College.

The paper describes a series of observations of magnetic quality in various specimens of sheet iron and iron wire. A principal object was to determine the amount of energy lost in consequence of magnetic hysteresis when the iron under examination was carried through cyclic magnetising processes. Many cycles of B and H were gone through in the case of each of the specimens, the limits between which B was reversed being varied step by step in successive cycles, to allow the relation of the energy expended or of $\int H dI$ to B to be determined. The iron examined was, for the most part, thin sheet metal or wire such as is used in the construction of transformer cores. The experiments show that there are marked differences in the values of $\int H dI$ in different specimens, even when all are nominally soft iron.

In connection with these results a formula proposed by Mr. C. P. Steinmetz $\left(\int H dI = cB^{1.6}\right)$[1] to express the relation of the hysteresis losses to B is discussed, and it is shown that although such a formula may serve fairly well as an approximate statement of the relation within those limits of B which are important in practice, it fails when applied to the more extreme portions of the curve.

The authors go on to describe a second group of experiments, in which direct measurements were made of the heat developed by magnetic reversals. The method consisted in using two rings, alike in all respects, with divided magnetising coils. One ring had its coils coupled so that the two parts opposed each other, and the core was consequently not magnetised when a current passed. The other ring was active, and its coils (coupled inductively) were connected in series with the non-inductive coils of the inactive ring. Alternating currents were passed through both, and the active ring became heated by the effects of hysteresis and Foucault currents. To balance this a steady current was caused to flow in the core of the inactive ring, and the energy was measured which had to be expended by this current in order that the temperature of the two rings might continue equal. In some cases the rings used were miniature transformers, and no difference was found in the amount of energy consumed in the core when the "load" was taken off or put on the secondary.

[1] "Trans. American Inst. of Electrical Engineers," vol. ix. No. 1.

In a third group of experiments the magnetic curve tracer was used to examine certain features of the curves of magnetisation. This instrument, invented by one of the authors, draws curves which exhibit the relation of the magnetisation of given samples of iron or steel to the magnetising current. Amongst other points referred to in this connection is the time-lag in magnetisation, which is shown by the curve tracer to be immensely great in soft thick bars. The work spent per cycle is a maximum at a particular frequency, which in such bars is very low.

The fourth and last section of the paper relates to the molecular theory of magnetisation, and describes experiments made with groups of small pivoted magnets. Results are given which tend to confirm the theory.

The particulars of the observations are set out in about forty sheets of curves which accompany the paper.

SYDNEY.

Royal Society of New South Wales, May 3.—Annual Meeting.—Prof. Warren, President, in the chair.—The report stated that thirty-three new members had been elected during the year, and the total number on the roll on April 30 was 477. During the year the Society held eight meetings, at which the following papers were read:—Presidential address, Hailstorms, and is Mars inhabited? by H. C. Russell, F.R.S.—On the importance and nature of the Oceanic languages, by Sidney H. Ray.—On certain geometrical operations, Part I., by G. Fleuri.—A determination of the magnetic elements at the Physical Laboratory, University of Sydney, by C. Coleridge Farr.—Analyses of some of the well, spring, mineral, and artesian waters of New South Wales, and their probable value for irrigation and other purposes, by John C. H. Mingaye.—Ventilation of sewers and drains, by John M. Smail.—Flying-machine work and the ¼ I.H.P. steam motor weighing 3¼lbs., by Lawrence Hargrave.—The venom of the Australian black snake (*Pseudechis porphyriacus*), by Dr. C. J. Martin and J. McGarvie Smith.—On the effect which settlement in Australia has produced upon indigenous vegetation, by Alex. G. Hamilton (for which essay the Society's bronze medal and prize of £25 were awarded).—Some folk-songs and myths from Samoa, translated by the Rev. G. Pratt, with introductions and notes by Dr. John Fraser.—Preliminary note on limestone occurring near Sydney, by Henry G. Smith.—Observations on shell-heaps and shell-beds, significance and importance of the record they afford, by E. J. Statham.—Notes on the recent cholera epidemic in Germany, by Dr. Schwarzbach.—On native copper iodide (Marshite) and other minerals from Broken Hill, New South Wales, by C. W. Marsh.—On the comet in the constellation Andromeda.—Results of observations of Wolf's Comet (II.), 1891, Swift's Comet (I.), 1892, and Winnecke's Periodical Comet, 1892, at Windsor, New South Wales, by John Tebbutt.—On the languages of Oceania, by Dr. John Fraser.—Notes on some Australian stone weapons, by Prof. Liversidge, F.R.S. The following papers were read before the various sections, viz.:—Medical Section: Recent work on the pathology of cancer, by Dr. G. E. Rennie.—Notes of a case of hydatid of the brain, by Dr. W. Chisholm.—Notes on a case of sarcoma of the testis in a cryptorchid removal, by Dr. Fiaschi. Engineering Section: Description of the engines recently erected at Ryde Pumping Station, with results of the tests applied, by C. W. Darley.—Various systems of tramway traction, by W. F. How.—Recent bridge-building in New Zealand, by A. H. Alabaster.—Notes on the economical use of steam, by T. H. Houghton.—Light railways for New South Wales, by C. O. Burge. Chemical and Geological Section: An account of a visit to New Guinea, together with some notes on the community of life between Australia and New Zealand, by Charles Hedley.—On the occurrence of platinum and associated minerals in the sands of the Richmond river; also in the lode material of Broken Hill, by J. C. H. Mingaye.—On a remarkable specimen of auriferous quartz containing fossil encrinites.—An account of some intrusive rocks in the neighbourhood of Sydney, by Rev. J. Milne Curran.—On a new mineral containing iodide of copper found at Broken Hill, by W. M. Hamlet.—The Clarke medal for 1893 had been awarded to Prof. Ralph Tate, University, Adelaide. The Council had issued the following list of subjects, with the offer of the Society's bronze medal and a prize of £25 for each of the best researches, if of sufficient merit, to be sent in not later than May 1, 1894:—On the timbers of New South Wales, with special reference to their fitness for use in construction, manufactures, and other similar purposes.—On the raised sea-beaches and kitchen middens on the coast of New South Wales.—On the aboriginal rock-carvings and paintings in New South Wales. To be sent in not later than May 1, 1895: On the silver ore deposits of New South Wales.—On the physiological action of the poison of any Australian snake, spider, or tick.—On the chemistry of the Australian gums and resins. The chairman read the Presidential address, and the officers and council were elected for the ensuing year, Prof. T. P. Anderson Stuart being President.

PARIS.

Academy of Sciences, July 24.—M. de Lacaze-Duthiers in the chair.—Diverse considerations on the theory of luminous waves, by M. J. Boussinesq.—Researches on samarium, by M. Lecoq de Boisbandran.—On the alleged fossil ferns of the coarse Parisian limestone, by M. Ed. Bureau.—On the distribution of the intensity of gravitation on the surface of the globe, by M. Defforges. This memoir has been submitted to the judgment of the Academy by the Minister of War. It contains a summary of the observations of the value of g at thirty-five stations, twenty-six determinations having been made with the "reversible invertible" pendulum invented by Commander Defforges, which eliminates the error due to the sliding of the knife edges. In this pendulum a displacement of the centre of gravity takes the place of the interchange of knife-edges, and the influence of curvature and of any dissymmetry in the action of the air is avoided. In the list of values enumerated, extending from Spitzbergen to Scotland, England, France, Corsica, and Algiers, there are certain anomalies which cannot be explained by supposed inaccuracies of observation and reduction. Clairaut's law, true in general, is almost everywhere masked by these anomalies. On the littorals of the various seas, gravitation presents slight anomalies, which are constant on the same coast, and characteristic of it. The islands show a considerable excess of gravitational force. On the continents the reverse obtains, and the defect appears to grow with the altitude and the distance from the sea. As the real surface of the ellipsoid, according to Clarke, does not depart from the theoretical surface by more than 18·4 feet from the Shetlands to the Mediterranean, the discrepancies cannot be attributed to irregularities in the figure of the earth, but must probably be accounted for on geological grounds.—Observations of Rordame's comet, made with the *equatorial coudé* (0.32m.) of the Algiers observatory, by M. Rambaud.—On the equations of the second degree whose general integral is uniform, by M. Paul Painlevé.—On certain systems of ordinary differential equations, by M. A. Guldberg.—On a nomographic method applicable to equations which may contain up to ten variables, by M. Maurice d'Ocagne.—Density of sulphurous anhydride, its compressibility and expansion in the proximity of normal conditions, by M. A. Leduc. The density of sulphurous acid under normal conditions was found to lie between 2·2638 and 2·2641. The coefficient of expansion between 0° and 20° was, at normal pressure, 0·003963, and at a pressure of 334mm., 0·003787.—On residues of polarisation, by M. E. Bouty. For defining capacities of polarisation it is implicitly admitted that, at least to a first approximation, the whole quantity of electricity which traverses the voltameter circuit during charge is employed in establishing polarisation, and will be recovered during discharge; also that to a given polarisation there corresponds a single and unique value of recoverable charge. M. Bouty shows that the effective capacities of discharge increase in proportion as the polarisation of the voltameter decreases. Even the initial capacities of polarisation cannot be relied upon to give rigidly constant values.—On some new interference fringes which are strictly achromatic, by M. Georges Meslin.—On the oxidation of sulphide of nickel, by M. Ph. de Clermont.—On crystallised cuprous phosphide, by M. A. Granger.—On bismuth subgallate (dermatol), by M. H. Causse.—On the condensation of the alcohols of the fatty series with the aromatic carburets, by MM. A. Brochet and P. le Boulenger.—On the effects of the slow destruction of the pancreas, by M. E. Hédon.—On the interference of excitations in the nerve, by M. N. Wedensky.—Comparison between the anterior and posterior members of some Urodelæ, by M. A. Perrin.—A parasitic entomophagus of the European silk-worm, by M. E. L. Bouvier and G. Delacroix.—Further researches on coccidia, by M. P. Thélohan.—On certain facts which permit a comparison between the central nervous systems of the Lamellibranchiata and the Gasteropoda, by M. A. d'Hardiviller.—On the Rhizoctone of Lucerne, by M. A. Prunet.—On the glacial origin of the breccia of the coal-bearing basins of Central France, by M. A. Julien.—On two Turkish meteorites recently added to the Natural History Museum, by M. Stanislas Meunier.—Desert sands of Lower Egypt, by M. A. Andouard. An analysis of the sands between the Ismailia canal and the Menzaleh Lake showed them to consist of 96·5 per cent. silica, 0·384 water, 0.507 organic matter, and small quantities of other substances such as carbonic acid, alumina, lime, and ferrous oxide. These deserts are gradually being reclaimed by irrigation and by the use of the "black earth" gathered among the ruins of ancient habitations.

GÖTTINGEN.

Royal Society of Sciences, February 22.—H. Weber: Researches in the theory of numbers in the domain of elliptic functions, II. A. Hurwitz: Proof of the transcendency of the number e. H. Burkhardt: On vector-functions which are themselves vectors, an application of invariantal methods to a question of mathematical physics. W. Holtz: On the immediate perception of magnitude in its relation to distance and contrast. W. Ramsay: The isomorphic stratification and the intensity of double refraction in epidote.

THE PROTECTION OF WOODLANDS.

The Protection of Woodlands. Authorised translation by John Nisbet, D.Œc., of the Indian Forest Service, of Kauschinger's "Waldschutz." Revised by Dr. Hermann Fürst. One volume, demy 8vo, 252 pages. (Edinburgh: David Douglas.)

FOREST Protection, termed *Waldschutz* or *Forstschutz* in German, is the art of protecting woodlands from external dangers, such as injurious meteoric influences, bad soils, injurious plants and animals, and human agency. The subject ranks in Germany as a separate branch of Forestry, distinct from silviculture, utilisation of forest produce, or forest management. In France, however, this is not yet the case; and the dangers to which forests are liable, together with the various preventive and remedial measures which experience suggests against them are described under the heads of forest botany, zoology, forest law, silviculture, and forest utilisation.

A strong reason for this difference of treatment of the same subject in the two countries is that the professors of subjects taught as auxiliary to Forestry at the French National Forest School at Nancy are experienced forest officers, but these subjects in Germany are taught by scientific specialists who have not sufficient forest experience to enable them to estimate the amount of damage likely to occur to forests from any form of injury, and the permissible limits of time and money in combating it. There is much to be said in favour of foresters studying botany and entomology from a general point of view and attending lectures on these subjects by eminent professors, instead of by foresters who may have worked up a branch of natural science more or less thoroughly, but it then becomes necessary that *Forest* Protection should be studied in a manual written by an experienced forester. The chief danger to the writer of a manual of forest protection is that he may be tempted to give undue preponderance to one branch of the subject, and in the work under notice the account of forest insects extends over 108 pages out of 246. This may be warrantable in Germany, where forest insects are unusually numerous and destructive, but in a treatise intended for practical use in the British Isles only confusion and bewilderment can result when insects which are destructive to forests in Central Europe, many of which do not exist here, while others that are rare and occur under different conditions, are described without any comment.

Mr. Nisbet has, in the section treating of forest offences, omitted certain matters relating only to German conditions of forestry. He should have carried his omissions further. No purpose is served by the inclusion of species such as *Chrysobothris affinis*, *Deudroctronus micans*, *Cnethocampa processionea*, &c., all unknown to the British forester, nor of varieties like *Tomicus sexdentatus*, *Lytta vesicatoria*, *Agelastica alni*, *Ocneria dispar* (apparently extinct), the Agrili, &c., unless the statements made are qualified by foot-notes, or otherwise. It is misleading to say that *Myelophilus minor*, whilst remaining unknown in many localities, often occurs in very large numbers in other places, whereas but a single British specimen is known; or that *Polyphylla fullo* occurs rather frequently here and there throughout sandy districts. A few species, though not British, like *Gastropacha pini*, or of rare occurrence, like *Tomicus typographus*, deserve notice in any boo dealing with forest entomology, provided that the freedom from them of our British woodlands is pointed out. This is done for the latter insect alone. If Mr. Nisbet had omitted about half the insects which he includes, he would have space to extend the diagnoses of the remaining species, which are too meagre to be of any use, and are little assisted by the roughly-coloured copies of some of the figures in Ratzeburg's "Forst Insecten." To give some account of insect attacks and methods of treatment in Britain, some species have been added, which, though rarely important, have occasionally annoyed tree-growers in this country, such as *Tomicus acuminatus*, *Earias chlorana*, *Pygaera bucephala*, *Sesia sphegiformis*, and particularly the wire-worms and millepedes often most destructive to seedlings. Many general statements appear which require modification, as, for instance, "in the *Diptera*, instead of any cocoon, a sort of bladder or shel is formed by the last larval skin"; and in the timber-boring *Scolytidæ*, "the larvæ hollow out short cone-like galleries at right angles to the main gallery," which is only true of *Trypodendron*, and not of *Xyleborus* or *Platypus*. Mr. Nisbet follows the German phraseology closely in his translation with curious results, such phrases as "raw localities," "ovi-depositor," "rostral beetle," seed owlet moths (*Agrotidæ:—Saat Eulen*) "multannual," are not welcome additions to the English language. One does not make "sections" of caterpillars to discover the presence of ichneumon larvæ; the Longicornia are not "cervicorn," but capricorn beetles; and the name Gold Beetle applied to *Clerus formicarius* is unintelligible.

The accounts of some of the more important insects, such as *Curculio abietis*, the cockchafer, and *Liparis monacha* (unimportant in Britain), are good, and the treatment recommended is in accordance with sound forestry; the section on decoy trees is one of the best, but if another edition is called for, the translator should submit the chapters dealing with forest insects to a competent entomologist and alter them so as to give a just account of forest entomology in Britain.

As regards the remaining parts of the book, in the account of the damage done by winds, "the system of cutting free or strengthening," *Loshieb* might have been rendered by the term *severance felling*, as proposed by Brandis in his notes on forest management in Germany published in 1888 by the India Office. Mr. Nisbet states that this system has not up to the present time enjoyed any very extensive adoption; but it is a fact that severance fellings are extremely common in the forests of Saxony. The term Scotch pine is surely preferable to that of Scots pine; and the English names of several birds on page 115 require revision. *Corvus frugilegus* is the rook and not the raven, and *Monedula turrium* is the jackdaw and not the rook.

The book is well printed and of useful size, being very similar in these respects to Dr. Schlich's manual of forestry, and apart from the chapter of forest insects, it will be very useful to the practical forester and to other students of forestry. The annexed table of contents explains its general scope—

Section First. Protection of Woodlands against Injuries due to Inorganic Agencies.—Chap. I. Damage caused by unusually High or Low Temperature. (*a*) Frost. (*b*) Heat. II. Damage caused by Atmospheric Precipitations. (*a*) Rain. (*b*) Snow. (*c*) Hoar-frost, ice, hail. III. Damage caused by Aerial Currents. IV. Damage caused by Lightning. V. Disadvantages arising from Unfavourable Soil and Situation. (*a*) Excess of moisture; wetness. (*b*) Deficiency of moisture; dunes, sand-drifts. VI. Diseases of Timber Trees.

Section Second. Protection of Woodlands against Injuries due to Organic Agencies.—Chap. I. Damage caused by Plants. (*a*) Noxious forest weeds. (*b*) Parasitic plants. II. Damage caused by Animals. (*a*) Mammals. (*b*) Birds. (*c*) Insects. (*a*) On coniferous trees principally. (*b*) On broad-leaved trees principally.

Section Third. Protection of Woodlands against Human Agencies.—Chap. I. Protection of Forest Boundaries. II. Protection against Misuse of Rights or Servitudes. III. Protection against Forest Offences and Misdemeanours. IV. Protection against Forest Fires. V. Protection against Damage by Smoke and other Atmospheric Impurities.

NORTH AMERICAN BUTTERFLIES.

Brief Guide to the Common Butterflies of the United States and Canada. Being an Introduction to the Knowledge of their Life-histories. By Samuel Hubbard Scudder. (New York: Henry Holt and Co., 1893.)

The Life of a Butterfly. A Chapter of Natural History for the General Reader. (Same author and publisher.)

IN the two small volumes before us Dr. Scudder, the author of the greatest monograph on any limited butterfly-fauna that has yet appeared ("The Butterflies of the United States and Canada"), has attempted the no less useful task of popularising the subject for the less advanced student.

Far more attention is paid in America than in Europe to the life-histories of insects, and the plan of Dr. Scudder's "Guide" is sufficiently indicated by the author in his preface. "I have accordingly selected the butterflies—less than a hundred of them—which would almost surely be met with by any industrious collector in the course of one or two years' work in the more populous Northern States and Canada . . . . As the earlier stages of these insects are just as varied, as interesting, and as important as the perfect stage, descriptions are given of these . . . . only such stages as would be more commonly met with being fully described, and the egg and earliest forms of caterpillar omitted as rarities, and also as too difficult for the beginner's study."

Those who know the thorough character of Dr. Scudder's work will not be surprised to learn that even within the narrow limits laid down, the book contains a far larger amount of general information than would be found in almost any popular European manual on a similar subject. Not that such information respecting our European butterflies does not exist, but it is scattered through thousands of volumes of periodical literature, and has hardly yet been properly systematised for the advanced student, much less for the beginner.

The introductory portion of Dr. Scudder's work consists of general information respecting butterflies in their various stages, separate keys to the American genera, both for the perfect insect and for the caterpillar and chrysalis, an explanation of neuration with a diagram, &c., &c.

In the body of the work each species occupies from one to two pages. It is first described as butterfly, caterpillar, and chrysalis, and then a full account of its life-history, habits, localities, times of appearance, &c., in all its stages, from egg-laying onwards, is given in larger type. An appendix contains instructions for collecting, rearing, preserving, and stuffing, extracted from one of Dr. Scudder's former works.

Dr. Scudder is rarely to be found tripping, but we think that the section on the senses of insects is hardly abreast of our present knowledge of the subject. On p. 23 he says, "The sounds made by butterflies are apparently due simply to the rustling of the wings." If he will refer to the work of an eccentric writer, but a good observer (Mr. Swinton's "Insect Variety," pp. 112-127), he will find a good deal of information about the stridulation of butterflies.

The second work which we have to notice, though smaller, is perhaps of greater interest to the European entomologist. It deals with *Anosia Plexippus*, the Monarch or Milk-weed Butterfly, one of the largest and most abundant of North American butterflies, a migratory insect which is rapidly extending its range over the warmer parts of the world.

It has been selected as a butterfly whose life-history presents more interesting points than that of most others (though other butterflies are, of course, referred to in the course of the work), and the following are some of the principal points which Dr. Scudder discusses in reference to it: the tongue, course of life, vagrancy, critical periods, mimicry, scent-scales, insect vision, the fore-legs, the position of the chrysalis, the proper name, &c.

It is now pretty well ascertained that this butterfly has as regular an annual migration as birds in North America from south to north and north to south. No lepidopterous insect probably possesses the habit to anything like the same extent; for the migrations of the day-flying moths of the genus *Urania*, though regular, are confined to comparatively narrow limits in the tropics.

We will now notice a few points that have struck us in glancing through the book. At p. 64, Dr. Scudder says: "There were certainly no butterflies here when the country was flooded with ice." Is not this too sweeping a statement? Have not our Arctic explorers found butterflies as far north as they have yet succeeded in penetrating?

It is pretty well known that newly-hatched caterpillars generally devour the shell from which they have just emerged. This has usually been regarded as merely an odd habit; but Dr. Scudder suggests that its real object may be to avoid betraying the proximity of the larva to its enemies by leaving the empty eggshell as an indication of its presence (p. 70). Scent is considered by Dr. Scudder to play an extremely important part in butterfly life. There are, of course, great differences in the structure of the eyes of different insects, but there is reason to believe that it is often very defective, and that its imperfect character is supplemented by a highly delicate sense of smell. A curious account of wasps chasing flies is given at p. 122, which seems to show that wasps at least are not the highly-endowed and intelligent creatures which some have been disposed to imagine. Yet the sense of smell in insects may be mistaken, as witness the well-known fact (which Dr. Scudder has forgotten to mention) that carrion-feeding flies will sometimes lay their eggs on foul-smelling plants. He finally sums up his remarks on the senses of butterflies as follows:—"It becomes clear that the exquisite beauty and variety in the butterfly world is not recognised by themselves, and form no element in their lives."

While agreeing with Dr. Scudder in the main as to his remarks on nomenclature, we are not quite sure that he is correct in applying Linné's name *Plexippus* to the butterfly in question. It is certain that Linné confounded two or three species under the name, among which was the Milk-weed Butterfly, and gave the locality as North America; but the words "Alæ primores fasciâ albâ, ut in seq. (*Chrysippus*) cui similis," seem to us to indicate that the name would be more correctly applied to an East Indian species; for no American species of the group agrees with the characters which we have quoted.

In reference to what Dr. Scudder says on p. 178 respecting the origin of the Pacific immigrants, we may mention that, to the best of our recollection, all the specimens of the butterfly which we have seen from any part of the Old World belong to the normal type of the United States.

The book is illustrated with four plain plates, representing the insect in its various stages, and numerous details.

In America, at least, entomologists are fast outgrowing the time when nothing was thought worthy of attention but the perfect insect. We imagine that the time is not far distant when no account of an insect will be regarded as *complete* which does not include its external and internal anatomy in all its stages as well as its life-history. W. F. KIRBY.

OUR BOOK SHELF.

Life with Trans-Siberian Savages. By E. Douglas Howard, M.A. (London: Longmans, Green, and Co., 1893.)

AWAY beyond Siberia proper, in the Okotsk Sea, lies the island of Saghalien, or Sakhalin. Acquired by Russia many years ago, it has been converted into a vast prison, in which to confine convicts, for whom transportation to the mines of Siberia is considered insufficient. To this island, even the name of which is whispered in fear in Russia, Mr. Howard was fortunate enough to gain access. Walking through the exile hospital one day, he saw a being unlike any he had met before, and which, it was afterwards explained to him, was a female of the race of Sakhalin Ainus—the aborigines of the island, and the progenitors of the Ainus of Japan. Mr. Howard was naturally fired with the desire to see more of the race, which possesses the distinction of being as simple in their savagery to-day as they were three thousand years ago. The book before us tells the tale of his journey to the Ainu country and his life among the people. The story is full of interest, and is told in an unaffected manner, without any straining after effect. As an example of the author's style the following account of the aboriginal method of procuring a light will suffice:—

"A rough little apparatus was produced, consisting of two little blocks of wood. Between these was placed a bit of very dry elm stick, one end, which we will call the lower end, being pointed so as to fit loosely into a hole in the lower block; the other end, also pointed, being in contact only with the flat under surface of the upper block. A bow was then unstrung at one end, the string was passed round the middle of the dry stick, and the free end was loosely re-attached. The bow was then worked with wonderful celerity, until the lower end of the stick first smoked, and then passed into a fitful blaze. This was communicated to some fine dry twigs, and in a few minutes we had as good a bivouac fire as I could wish."

Mr. Howard witnessed the manufacture of the poison used by the Ainu for tipping arrow-heads. His description brings to mind the witches' caldron in *Macbeth*. An infusion produced from dead spiders was mixed with inspissated gall of foxes, and a thick extract of the roots of *Aconitum napellus*, in order to procure the deadly paste. It has been said that the Ainus of Japan perform no religious ceremonies during the preparation of these ingredients, but Mr. Howard's observations show that the Ainus of Sakhalin certainly do sanctify them. After preparation the paste is pressed into a long and deep hollow in the arrow-head, and its poisonous properties are preserved by smearing the head with a resinous gum. The secret of manufacture is only known to the two chiefs of the village and two arrow artificers.

There are many other points of interest in Mr. Howard's narrative, especially to the student of ethnology. In fact the book appears to be a "plain, unvarnished tale" of personal observations, and on this account, if for no other reason, it is well worth reading.

Advanced Physiography. By R. A. Gregory and J. C. Christie. (London: Joseph Hughes and Co., 1893.)

TEACHERS have long felt the need of a good text-book on advanced physiography, and will no doubt fully appreciate the little book before us. Mr. Gregory's twelve chapters on the astronomical side of the subject form an admirable supplement to his now well-known "Elementary Physiography." This part of the book is treated in a very practical manner, and the text is at the same time remarkably free from errors; one mistake, however, is in placing β Cassiopeiæ amongst the bright-line stars instead of γ Cassiopeiæ. The various astronomical instruments are described in a clearly-written and well-illustrated chapter, which should prove extremely useful to students who have not the advantage of seeing and using the instruments for themselves. In all the most recent discoveries the book is well up to date; in the chapter on "Stars and Nebulæ" a racy account is given of the discovery, observations, and probable origin of the new star in Auriga. The author writes with a practical knowledge of his subject, and has done as much justice to it as the limitations of a text-book allow.

Mr. Christie is responsible for the three final chapters, dealing with the earth as a cooling globe in relation to Kant's hypothesis. The treatment adopted is more of the nature of an essay than that of a text-book; but, as pointed out by the author, this is chiefly due to the fact that the subject is to a great extent speculative. The table of the terrestrial elements known to occur in meteorites and other celestial bodies might have been of value if sufficient care had been taken to insure accuracy. As regards the elements in the sun it differs very widely from the table given by Mr. Gregory on p. 185, and several elements, such as bromine, are erroneously included.

The 107 illustrations form a noticeable feature of the book, many of them having been specially drawn for it. We confidently recommend the book to the notice of teachers, for it is certainly one of the most excellent expositions of the subject that we have yet seen.

Proceedings of the Edinburgh Mathematical Society. Vol. xi. (London: Williams and Norgate, 1893.)

THE practice recently adopted by this Society of issuing its volumes in complete form at the end of its session, whilst it has some advantages, has the great disadvantage which results to an author in the long delay of the publication of his results if he has made his communication early in the session. We believe, however, that the Society meets this objection by allowing authors to have copies of their papers as soon as they are printed.

There are twelve contributors to this volume of 170 pages. The historical notes are especially interesting. They are on the history of the Fourier series, by G. A. Gibson; history of the nine-point circle, early history of the symmedian point, and Adams's hexagons and circles, by Dr. J. S. Mackay. These last are written in Dr. Mackay's usual interesting style, with full references to early writings on the several points. It is a pity that he has not received sufficient encouragement to publish his large store of notes in a single volume instead of issuing them in the shape of detached notes. Prof. A. H. Anglin gives a paper on certain results involving areal and trilinear coordinates. Mr. C. Chree writes on action at a distance, and the transmission of stress by isotropic elastic solid media, and Mr. W. Peddie contributes notes on the use of dimensional equations in physics, on the fundamental principles of quaternions and other vector analyses, and on the elements of quaternions. This last subject is discussed at some length by Prof. Knott in the quaternion and its depreciators. His attitude is well known to the mathematical readers of NATURE (see vols. for 1891-2-3). The remaining notes appeal to the mathematical masters, who form the major part of the *clientèle* of 131 members.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Publication of Scientific Papers.

THE discussion of this important subject has been started *à propos* of physical papers, but the publication of papers in all branches of science is in an equally unsatisfactory state.

Prof. Lodge, in his letter in your issue of July 27, after paying attention to the preparation of useful abstracts of all papers on physical subjects appearing both at home and abroad, calls attention to what has always appeared to me to be the most important matter for reform, namely, the means and methods of publication of English scientific papers.

There is no complaint more frequently heard abroad than that important papers of English scientific men are almost inaccessible to the foreigner, because it has been the fashion to communicate them to local societies and to rest content with such publication as is secured by their being printed in the Society's Proceedings or Transactions. If these societies distributed their publications liberally where there are students who ought to have the opportunity of reading them, and without taking account of whether they receive in exchange a publication of an equal number of pages, the evil would be much less. But this is not so. It is notorious—to take, for instance, the Royal Society of Edinburgh, with which I am best acquainted, and which is not by any means the least liberal in the matter of distribution—that unless the author distributes lavishly separate copies of his paper in every quarter where he considers it important that it should be read, it will pass unnoticed, and a worker in the same branch of science will not consider that he is open to any blame for not being acquainted with a paper published in an organ so difficult to procure. I believe that this applies in at least an equal degree to the other two societies mentioned by Prof. Lodge, namely, those of Dublin and Cambridge, and of course it is all the more applicable to societies of less importance. But even the Royal Society itself is open to exception in this respect, for although no fault can be found with the Proceedings or Transactions as a recognised organ of publication, they are, as a matter of fact, not more readily accessible abroad than the corresponding publications of the Edinburgh Society, and the majority of foreign students never see anything but abstracts of important English papers. The only independent scientific journal of importance is the *Philosophical Magazine*, and though widely known it is not extensively used, and has not grown with the times. The want of means of scientific publication which has been produced by the development of scientific activity in the last twenty or thirty years has been met by an increase in the number of societies, and by a greater development of society publication. The former is probably an advantage, the latter is certainly a disadvantage. The publication of scientific papers cannot be too much centralised in the interests of both authors and readers, and for this purpose a central organ such as indicated by Prof. Lodge is required.

What is at present inefficiently and extravagantly done by a multitude of amateur publishers scattered over the country could at much less cost be efficiently done by a central publishing officer issuing a central organ, in several series, each series appearing in monthly numbers, and the whole run on strictly business lines. Each series should be devoted to a particular science or branch of a science. Thus, there might be several series in chemistry as organic chemistry, inorganic chemistry, physical chemistry and technical chemistry. Physics also would fall into several series, as would other sciences. Each series of original papers would have a parallel one of abstracts of foreign papers on the same subject, and it would be useful to have a separate series, which might be issued weekly or fortnightly, devoted to printing a minute of the proceedings and papers read at the meetings of the various societies throughout the country, to be furnished by their secretaries.

The effect of the realisation of some such plan as this would be the immediate setting free of the large sum of money annually spent by the societies in printing, and the collection of all that is published in *one* organ, which would be an enormous assistance to the student.

Each series would have to be intelligently and liberally indexed, and a separate volume of the indices of all the series published each year. It would then be sufficient for the worker to take in the series devoted to his own branch of science and the yearly index volume, which would prevent his overlooking papers of importance appearing in other series.

This scheme of central publication has occupied my thoughts for some years, and I have from time to time discussed it with my friends, and it has even been brought before one publisher, but without any practical effect.

It is therefore with very great pleasure that I find Prof. Lodge advocating a similar scheme, and I hope that it may be the means of fixing public attention on the present unsatisfactory state of things and of forcing a remedy.

August 8. J. Y. BUCHANAN.

THE abstracts of physical science for the year 1886, published by the Berlin Physical Society, are contained in three stout octavo volumes, comprising over 2000 pages, while the somewhat less comprehensive supplements to the *Annalen* average about 1000 pages. A good index, on the other hand, can be prepared at little more than the cost of printing. An index entry, which contains the full title of the article, the name of the author, the correct reference, the number of pages covered by the article, and, where necessary, a brief indication of the scope of the article, is sufficient to inform the student where each advance in his particular branch of science is to be found reported, and is of permanent value to searchers of all sorts, provided a proper system of classification of the index entries is adhered to. The scheme of indexing carried out by the Association of Engineering Societies of America presents many features worthy of imitation. The index, which appears monthly in the journal, is printed on one side only (the reverse is available for advertisements) and possesses a separate pagination, so that a student can extract for himself any entries which he may require. At the end of the year the index is consolidated, so as to form a permanent record of the progress of the science during that period. The consolidation of the index can be cheaply effected by an arrangement with the printer to keep the type standing for twelve months, when, in addition to the reference to the source of the original paper, references to abstracts and reviews can be incorporated. If the Physical Society would undertake such a work, it is probable that the utility of the index would lead to an extension of the system to other sciences also. It is clear that by a cooperative arrangement between two or more societies various indexes could be issued at a relatively slightly increased cost. The economy is obvious: the same files have to be searched but once, the same staff would be competent to do the combined work at a cheaper rate, and minor economics could be effected in stationary salary of editor, &c.

It remains to be seen whether English physicists are disposed to abandon their present attitude of masterly inactivity—waiting until, in the fulness of time, International Bureaus shall step in and do the work for them. A simple scheme like the above requires no *deus ex machinâ* in the shape of British Association aid to set the ball rolling.

44, Blenheim Terrace, N.W., July 31.

The General Motions of the Atmosphere.

TWO cyclonic storms have occurred over the Indian region, the tracks of which appeared to be suggestive of the existence of very abnormal conditions in the general circulation of the currents of the atmosphere. The first storm appeared over the east of the Bay of Bengal, in about lat. 15° N., on May 20. The centre crossed the bay on a W.N.W. track during the 21st and 22nd, and appeared on the Orissa coast on the 23rd. Here it slowly recurved and followed a N., N.E., and E. course, finally passing away on May 29 or 30 into Assam and Manipur. The second storm appeared over the east of the bay, also in about lat. 15° N., on June 11, passed during the 12th, 13th, 14th, 15th, and 16th W.N.Westward across the bay, and to the centre of the Indian Peninsula. It there recurved, like its predecessor, through N. and N.E., and finally into E.

Combining the direction of movement of the two storms for each twenty-four hours after movement commenced we obtain the following figures:—

	Direction.		Direction.
1st day,	N. 80° W.	6th day,	N.
2nd ,,	N. 78° W.	7th ,,	N. 27° E.
3rd ,,	N. 52° W.	8th ,,	N. 50° E.
4th ,,	N. 36° W.	9th ,,	N. 70° E.
5th ,,	N. 13° W.		

The following is the normal movement of storms during the period May 20 and June 20, extracted from the "Handbook of Cyclonic Storms in the Bay of Bengal," by combining the directions of motion of each storm recorded within the period:—

	Direction.		Direction.
1st day,	N. 48° W.	5th day,	N. 48° W.
2nd ,,	N. 39° W.	6th ,,	N. 41° W.
3rd ,,	N. 40° W.	7th ,,	N. 22° W.
4th ,,	N. 55° W.		

It will be observed from this comparison that the direction of movement of the two storms of May–June, 1893, disagrees with the average movement of storms at this time of year. On the other hand, "recurving" from a N.W. translation, through a N. translation into a N.E. and E. translation is in the Indian region a marked feature of the progressive motion of storms in the spring and autumn months, and it hence follows that if the direction of movement of cyclones is controlled by the upper currents of the atmosphere, then the upper currents existing over the Indian region at the end of May and during the first half of June in the present year were analogous to those ordinarily prevailing over that region in the spring and autumn, and were not comparable with those normally prevailing at or about midsummer. Now, according to an hypothesis put forward by the writer, there exists over this thermal equator a current of westerly translation, and it is within this current, or on the margins thereof, that all the more important cyclones originate. On the north side of the current of westerly translation air currents exist, moving first to N.W., then to N., and finally towards N.E. and E., transferring the air raised over equatorial regions (or rather over the regions covered by the thermal equator) towards the temperate zone. In ordinary years nearly all the storms of the bay appearing between May 20 and June 20 appear to the north of lat. 18°, and the great majority of them to the north of lat. 20° N. At the same time the thermal equator and air-current of westerly translation at midsummer covers northern India, and its northern margin lies close to the Himalayan range of mountains. This range obstructs any northerly movement of cyclones, and hence the direction of motion of storms is controlled by the current of westerly translation, and is towards the west. In the spring and autumn, on the contrary, the thermal equator lies over southern India, and the motion of cyclones is—first westerly, within the equatorial current of westerly translation, and subsequently along the curved track described by the returning air. When, then, as in the present case, we have occurring nearly at midsummer a direction of movement of cyclones analogous to that prevailing in the spring and autumn, it may not be unfair to assume that the thermal equator, the return current of air from the torrid to the temperate zone and the massive current of easterly translation over the temperate zone, all lie to the southward of the positions occupied by them in normal years. If this be the case in the Indian region, it is conceivable that similarly anomalous conditions prevail in other parts of the world; and it is, perhaps, possible that the exceptional weather which has prevailed over the United Kingdom, and other portions of the north temperate zone, may be due to the fact that the United Kingdom, &c., relatively to that portion of the current of easterly translation which ordinarily transports cyclones eastward has been modified, and that this portion of the current, and consequently the path of cyclones, lie to the southward of their normal positions.

It is very difficult in India to accurately determine the lie of the thermal equator, as it is very doubtful if temperature observations at the earth's surface are in themselves sufficient to show the real atmospheric thermal conditions. Apparently, however, the centre of the thermal equator in May runs from about lat. 18° to 20° N. in long. 96° E. to lat. 25° N. in long. 68° E. The writer has extracted from the monthly weather review the temperature (day temperature) anomalies of three stations (Calcutta, Allahabad, and Lahore) lying to the north and of three stations (Nagpur, Madras, and Bombay) lying to the south of the line given above, and finds they are as follows:—

$$\text{Northern Stations.}\left\{\begin{array}{l}\text{Calcutta} = -4^{\circ}\!\cdot\!2\\ \text{Allahabad} = -3^{\circ}\!\cdot\!0\\ \text{Lahore} = -1^{\circ}\!\cdot\!9\end{array}\right\} = -3^{\circ}\!\cdot\!1$$

$$\text{Southern Stations.}\left\{\begin{array}{l}\text{Nagpur} = -2^{\circ}\!\cdot\!4\\ \text{Madras} = +1^{\circ}\!\cdot\!3\\ \text{Bombay} = -0^{\circ}\!\cdot\!8\end{array}\right\} = -0^{\circ}\!\cdot\!6$$

These observations show negative anomalies for both regions but they would also appear to show, from the largeness of the anomaly to the north and the smallness of the anomaly to the south, that the line of greatest heat over India in May had been thrown to the southward. According to the writer's views, however, the low latitude of the place of origin of the cyclones and the subsequent curved trajectories of the storms are stronger evidences of the southerly position of the tropical band of westerly translation than that afforded by temperature observations taken at the earth's surface.

W. L. DALLAS.

Simla, India, July 2.

Thunderbolt in Warwickshire.

ON Sunday evening, July 2, this part of Warwickshire was visited by a very severe storm of thunder and lightning, accompanied by torrents of rain. After the storm had subsided, about ten minutes before ten o'clock in the evening, a fireball seems to have fallen in the village of Dunchurch, an occurrence still rare enough to warrant its being placed on record.

On the afternoon of July 4 I visited the garden of A. H. Harrison, Esq., of Dunchurch Hall, in which an explosion occurred at the time indicated, breaking off at about seventeen feet from the ground a fine specimen of Wellingtonia growing on the lawn, which had been when intact about thirty feet high. The upper portion was shivered, fragments being scattered far and wide both over the lawn and an adjoining field, some fragments sticking in the grass lawn and showing that they must have been hurled with great force.

At the same time twenty-four panes of glass in front of the house were smashed by the violence of the explosion, at a distance from the tree of twenty-three to forty-three yards.

It was noticed that windows of plate glass, as well as windows which happened to be open at the time, escaped. The explosion is said to have been quite unlike thunder, and to have resembled the report of a heavy piece of ordnance. It is probable that the report was heard here in Rugby, as I find that two persons who happened to be in my house at the time remember hearing a double report at about the same hour, which they remarked upon to each other as being like the distant firing of a cannon.

As to the evidence of the agent of destruction being a fireball, I have, through the kind help of Mr. Harrison, been enabled to examine four witnesses, all of whom agree that during an interval of two minutes before the explosion a large fiery globe was seen travelling through the air, and emitting light of such dazzling brilliancy that the only one of them who was out of doors at the time was for a moment blinded and dazed, and felt for some short time afterwards a sensation of pain in the back of the head and the neck.

A fifth witness, whom I did not see, was at the time of the explosion in a room overlooking the lawn on which the tree grew, and states that she saw through the drawn blind the reflection of a fiery round ball at the instant of explosion.

The ball seems to have been larger than any hitherto observed, all speaking of it as appearing larger than the sun or moon, and one of them said it was as large as an ordinary fire-balloon when seen at a short distance. The colour is said to have been of an intense fiery red, but a person who did not see the ball was startled almost at the instant of the explosion by the lighting up of a long passage in Dunchurch Hall by an intense blue light.

The path taken by the fireball during the two minutes it was observed could hardly have been direct, as the direction taken when first seen makes an obtuse angle with the direction indicated by all who saw it immediately before the explosion.

14 Bilton Road, Rugby. L. CUMMING.

P.S.—I have submitted a draft of this letter to Mr. Harrison, who agrees with me in the accuracy of the report given above.

The Suicide of Rattlesnakes.

I NOTICE in NATURE for June 1, 1893, page 107, an inquiry by Mr. R. I. Pocock as to the suicidal habits of scorpions. His conclusion is that if scorpions sometimes kill themselves, the verdict must be "accidental suicide, or suicide while of unsound mind." I have no evidence to offer as to the habits of Californian scorpions, but I have myself witnessed the deliberate suicide of a rattlesnake, and think that a brief account of it may be worth recording. In the summer of 1888 Prof. Keeler saw a large rattlesnake (with seven rattles) crawl under the foundation of the dome of the six-inch equatorial. With the nice manipulation for which he is famous, Dr. Keeler fastened a pair of blacksmith's tongs about the animal's neck, and brought him into the large marble vestibule of the observatory. The snake was furious and was practically uninjured. After every one had seen him it became a question what to do next. It was resolved to put him into a gallon jar of water. Dr. Keeler had the task of getting the very lively animal (which was some three feet long) into the jar, and of letting go with the tongs; while I undertook to put in the stopper of the bottle at an auspicious moment. All this was accomplished very nicely, and the next step was to drown the snake by inverting the jar at intervals. After a little time it became obvious to every one, the snake included, that the animal must soon be drowned. At this moment the snake ceased any attempt to rise to the surface of the water in the jar, and in the most deliberate manner struck its fangs deep into its body. I have no doubt whatever that the blow was intentional, and with suicidal purpose. It was a single deliberate blow. There was no flurry. As far as one could see the animal was of sound and disposing mind and memory. It had been full of fury at first, but latterly had only sought to escape from the water to the air at the top. When this became hopeless the snake ended its own struggles. I had often heard that snakes (and scorpions) put an end to their own lives. Here is an instance which occurred before my eyes. The snake is now preserved in alcohol at the observatory, and the marks of the fangs are plainly to be seen.

Lick Observatory, July 19. EDWARD S. HOLDEN.

New Conclusions.

IN the last volume of the Proceedings of the Royal Society of Victoria, a paper appears by us entitled "Preliminary Account of the Glacial Deposits of Bacchus Marsh." In this paper we claimed to have shown that there were two distinct deposits of till separated by sandstones assigned to the Triassic age, and moreover that the upper till rested on the denuded surface of the latter.

Further examination has shown that we were mistaken as regards the last point. Our conclusion had been drawn mainly from a section which we have described and figured as occurring at a small quarry on the Korkuperrimul Creek. At this place we described till as overlying, and a granite boulder over a yard in diameter, together with smaller boulders, as being jammed into, the broken surface of the sandstone.

The real state of things is that the clay material containing the boulders is really a bed intercalated with the sandstone, the whole being inclined at about 35°–40°. What was described as till overlying these sandstones turns out to be a "wash" containing striated stones, and derived from an outcrop of a till like deposit a little above. Besides the larger clay bed containing the large boulders, there are several other thin bands of clay intercalated with the sandstone containing pebbles, several of which we found to be striated.

The real succession in this locality would now appear to be as follows:—

(1) Till, undoubtedly morainic, and probably resting on silurian rocks.

(2) Shales.

(3) Massive sandstones with intercalated bands of clay bearing transported boulders.

(4) A till-like deposit containing boulders.

(5) Shales and well-stratified fine argillaceous sandstones.

It would be unwise to assume that this succession represents the general order in Victoria, as stratified deposits associated with till may be of local significance only.

As the fossil evidence so far obtained points to the sandstone being of fresh-water origin, it seems reasonable to suppose that it was deposited in a glacial lake into which sub-glacial streams flowed, and in which floating ice wandered, dropping boulders here and there. At the quarry above-mentioned, the clay bed containing the large boulders, and the sandstone adjacent to it, are remarkably contorted as if an iceberg had grounded there.

As to the real nature of the till-like deposit referred to as overlying the sandstone, we do not yet care to speak definitely. It presents some strong points of resemblance to true till, but it may be of aqueous origin aided by floating ice.

It will be now seen that the sandstones known as the Bacchus Marsh Sandstones must be considered as part of the glacial series. Our friend Mr. Charles Brittlebank has also come to this conclusion quite independently of us. Of course the other sections given with our paper will have to be altered in accordance with the foregoing.

Having recently had an opportunity of seeing the glacial deposits near Heathcote, described by Mr. Dunn last year, we may say that there, as at Bacchus Marsh, the lowest member, at least, is a true till due to the action of land-ice. We cannot agree with Mr. Dunn in his opinion that these deposits are entirely an iceberg drift.

A notable point of difference between the till at Bacchus Marsh and that at Heathcote, lies in the immense quantity and variety as well as the great size of the rock-debris in the latter locality. Mr. Dunn well expresses it when he says that it looks as if the ruins of a continent were gathered here. It would almost seem as if Heathcote were in the region of a terminal moraine. The somewhat unsatisfactory evidence afforded by the "roche moutonnée," known as Dunn's rock, seems to indicate that the ice came from the south in this district.

GRAHAM OFFICER.
Melbourne University, July 4. LEWIS BALFOUR.

THE THIEVING OF ASSYRIAN ANTIQUITIES.

SO much interest is now taken in the archæological researches made in Egypt and Assyria that it behoves a journal of science to chronicle a case of considerable importance that has recently been before the law-courts. The case is noteworthy, because it is concerned with the excavation and disposal of the wonderful tablets, the decipherment of which has added so much to our knowledge of the early history of mankind.

We have not referred to the case earlier, as we had hoped that some action in the public interest would have been taken by the Trustees of the British Museum, which would have carried the matter a stage further. For this action however we have waited in vain.

Although the real question at issue is the spending of many thousands of public money, the case in the newspapers has taken the form of an action for libel. The plaintiff in the case was Mr. H. Rassam, formerly assistant-excavator to Sir Henry Layard in the works carried on for the trustees of the British Museum on the sites of the ancient cities of Nineveh and Calah in Assyria. His action was against Dr. Wallis Budge, acting Assistant-Keeper in the Department of Egyptian and Assyrian Antiquities in the British Museum. It was alleged that Dr. Budge had made certain reports concerning the way in which Mr. Rassam had disposed of some of the excavated antiquities, and that these statements were made to Sir H. Layard both at the British Museum and elsewhere. The statements were said to imply that Mr. Rassam had connived at depredations on the sites of the excavations made by him in Babylonia during the years 1876-82 for the trustees of the British Museum. Mr. Rassam estimated that his reputation had suffered by these charges to the extent of £1000, and after a hearing of four and a half days the jury decided in his favour, though there was a difference of opinion among them as to whether Dr. Budge's statements were actuated by *malice prepense*, and awarded him £50 to make up for the loss sustained by the defamations and to soothe his virtuous indignation. Such was the case before the public; the public interests behind it may be gathered from the following statement.

It will be remembered that so far back as 1846 Mr. Layard began to excavate at Kouyunjik for the trustees of the British Museum. These excavations had, we understand, been commenced at the expense of Sir Stratford Canning, on the spot where the eminent Frenchman, Botta, had begun to work, but were afterwards taken over by the trustees of the British Museum, who indemnified Sir Stratford Canning and paid Mr. Layard's expenses. When Mr. Layard came home, a year or two later, the excavations practically stopped, but were renewed at the expense of the trustees of the British Museum under the direction of a native, Mr. H. Rassam, the plaintiff in the present case. The funds spent by the trustees on these works were provided by the Treasury, and therefore all the results, without exception, belonged to the British Museum by right. In 1873 the late Mr. George Smith made an expedition to Assyria at the expense of the proprietors of the *Daily Telegraph*, with a view of discovering other fragments of the tablet containing the Assyrian account of the Flood. He subsequently made a second and a third expedition to the country (where, in 1876, he unfortunately died) at the expense of the trustees, with funds granted by the Treasury. In 1878 Mr. Rassam again appeared on the scene, and under the authority of a permit from Constantinople renewed diggings in Assyria, and began to open new sites near Babylon, at the expense of the British Museum. It will be seen then that, with very slight exceptions, the money has been found by the British Treasury. We now turn to the results of this expenditure. From the evidence elicited at the trial it appeared that soon after Mr. Rassam began to dig in Babylonia, collections of tablets found their way into the London market, and these were bought by the British Museum for considerable sums of money (*Times*, July 1). If we remember rightly Dr. Budge stated that between the years 1879 and 1882, while Mr. Rassam was excavating, a sum of at least £3000 of public money was spent in this manner. Now as no other excavations were being carried on except by the British Government, and as the internal evidence of the tablets indicated that those which they received from Mr. Rassam as the result of his works and those which they purchased had the same origin, it was natural that the public department should begin to grow uneasy. And this feeling became stronger when it was found that the tablets purchased were of much greater value archæologically and historically than those which arrived at the British Museum from Mr. Rassam. Speaking broadly, it seems from the evidence that Mr. Rassam sent home 134,000 pieces of inscribed clay from Babylonia, and of these more than 125,000 are what Sir Henry Rawlinson, Mr. Maunde Thompson, and Dr. Wallis Budge style "rubbish" (*Standard*, June 30, *Times*, July 3). This represented the direct return for the outlay. What did go wrong we cannot say, but the outsider will certainly think that something did go wrong in this matter. In 1882 Mr. Rassam came home, and in this and the following year collections of tablets and other antiquities of very great value were offered to the Museum for purchase; in fact the supply appears to have been so great that it was some three or four years before the British Museum had funds to buy what it was offered. In 1887 the British Museum despatched Dr. Budge to Mesopotamia with instructions to make investigations into the sources of the supply of tablets which were coming to London, and on many other points, to touch upon which does not concern us (*Times*, July 1; *Standard*, June 29). While in Bagdad Dr. Budge obtained a great deal of information upon the subject of the systematic trade in Babylonian antiquities which was being carried on, and he found that the agent who had been appointed at Mr. Rassam's instigation, and who represented himself as Mr. Rassam's "relation" (*Standard*, June 29), and who was paid by the British Museum to protect the sites, was himself actively engaged in the sale of antiquities. On visiting the sites of the excavations Dr. Budge found that clandestine diggings were going on, and he was also able to purchase many valuable tablets and other antiquities from the peasant diggers (*Times*, July 1). The information which he gathered on all these points he sent home to the British Museum in the form of reports, one of the results of which was the dismissal of the native agent. On two subsequent occasions Dr. Budge visited Assyria and Babylonia, and carried on excavations for the trustees, and he acquired some thousands of tablets.

It will easily be guessed that from first to last a very considerable sum of public money, amounting to tens of thousands of pounds, has thus been spent upon excavations in Assyria and Babylonia, and the question naturally arises, Has this money been spent judiciously, and has the nation obtained what it had a right to expect in return for its money? It seems pretty evident that people other than the trustees of the British Museum have obtained collections of Assyrian antiquities, and it appears to us that this subjeet should form the matter of a careful and searching investigation. Sales at auctions have revealed the fact that sundry gentlemen had been able to acquire Assyrian slabs from the palaces of Assyrian kings, and as the excavations were carried on by the Government, it is difficult to account for this fact. The public has a right to know how property of this nature came into private hands, and the question must be asked until it is satisfactorily answered. The matter cannot be allowed to rest where it is.

We have seen that it was stated at the trial that in consequence of Dr. Budge's reports the native agent has been dismissed for his pains. Dr. Budge has been mulcted by the verdict of the law-courts in a sum of something over, we hear, £1000. Hence arises another point of wide general interest regarding the treatment which should be accorded to confidential reports from subordinate officers by the higher officials. In the case with which we are at present concerned, Dr. Budge reported such things as he considered to be of importance for the information of his superior officers, and it was, one would think, their duty to sift such reports and to act upon them. For some reason or other, as we gather from the evidence at the trial, the trustees did not act upon them, from which fact Mr. Justice Cave inferred that Dr. Budge in repeating to Sir H. Layard part of the contents of his reports had repeated things which the trustees themselves had considered frivolous and trifling (*Times*, July 4). This, however, is no argument at all, for the reasons of the non-action of the trustees are unknown, and it does not follow that the trustees regarded them as vexatious and trifling. With the terror of the decision in this case before them, all members of the public service will be in duty bound to consider whether they are able to afford the expenses of an action at law, and the enormous costs which follow in its train, before they report unpleasant truths to their superiors. Who can complain if public servants, rather than incur the penalties of the law, hold back information they are in a position to give? Whether this will be good for the public service remains to be seen.

Mr. Justice Cave, referring to the depredations around the excavations, is reported to have said (*Standard*, July 4): "We all know that if you gave £300 for a cylinder like the one produced, it is an incentive for people to steal. It is like the poachers. They will take your own game if you will buy it of them, or they will take it anywhere they can get it." Mr. Justice Cave's facetious remark, however, is scarcely on all fours with the verdict of the jury. He owns that the excavating grounds in question are preserves belonging to the trustees of the British Museum; yet when a keeper reports in general terms that a large amount of poaching has been going on, he is heavily mulcted for his pains, because an individual chooses to assume that he was meant.

Here then are the facts; we believe that so far no action whatever has been taken by the Trustees; still we are glad to learn from the *Daily News* that Dr. Budge's *confrères* at all events have a sense of public duty. That paper states "that the keepers of departments and the assistants in the British Museum have combined to present Dr. Budge with a cheque in settlement of his damages in the recent libel action of 'Rassam *v.* Budge.' It is understood that this is not merely an expression of sympathy with a popular colleague, but that the action of the Museum officers was prompted by a strong feeling that as Dr. Budge has acted throughout in the interests of his department, it would be most unfair to allow him personally to suffer."

BRITISH ASSOCIATION MEETING IN NOTTINGHAM.

A FORTNIGHT ago some account was given of the local arrangements made for the entertainment of members of the British Association during their stay in Nottingham. The accommodation provided for the sections was also indicated. Fuller details on these matters will be found in the local programme now in course of preparation.

With regard to the more serious and useful functions of the Association, something of a preliminary and general character may now be stated.

It is with feelings of great satisfaction that members will welcome Dr. Burdon Sanderson as general president at Nottingham, and it will be unnecessary in a scientific periodical to refer to the eminent service which has been rendered to scientific progress by the president elect.

The acceptance of the following gentlemen of the positions of sectional presidents will also do much to ensure the success of the sections:—Mr. R. T. Glazebrook, Dr. Emerson Reynolds, Mr. J. J. H. Teall, Rev. Dr. H. B. Tristram, Mr. Henry Seebohm, Dr. J. S. Nicholson, Mr. Jeremiah Head, and Dr. H. Robert Munro.

In respect to these appointments universal regret will be felt at the inability of Prof. Clifton to fulfil the duties of the president's chair in Section A, which he had accepted, owing to serious family trouble. But the acceptance of the position by Mr. Glazebrook will beyond doubt cause general satisfaction.

The work of the sections will in part be connected with receiving the reports to be made by the various research committees. Amongst these the following subjects are included:—Electrical standards, meteorological observations on Ben Nevis, the application of photography to meteorology, calculation of tables of certain mathematical functions, recording direct intensity of solar radiation, wave-length tables of the spectra of the elements, an international standard for iron and steel analyses, the direct formation of haloids from pure materials, action of light on dyed colours, isomeric naphthalene derivatives, erratic blocks in England, the fossil phyllopoda of palæozoic rocks, the collection of geological photographs, the circulation of underground waters and their use as water-supplies, the zoology of the Sandwich Islands and of the West India Islands, exploration of the Irish Sea, the inhalation of oxygen in asphyxia, methods of economic training, exploration of ancient remains in Abyssinia, the characteristics of natives of Canada and of India, the recalescent points in metals, volcanic phenomena in Japan, the Pellian equation, the discharge of electricity from points, comparing and reducing magnetic observations, optical constants of lenses, ultra-violet rays of the spectrum, meteoric dust, rate of increase of underground temperature, the bibliography of solution and the properties of solutions, the bibliography of spectroscopy, the silent electrical discharge in gases, the action of light on the hydracids of the halogens in presence of oxygen, the proximate chemical constituents of various kinds of coal, the history of chemistry, the erosion of sea-coasts in England and Wales, the volcanic phenomena of Vesuvius, type-specimens of British fossils, investigation of the remains in Elbolton Cave, structure of a coral reef, the migration of birds, the protection of wild birds' eggs, the teaching of science in elementary schools, graphic methods in mechanical science, prehistoric and ancient British remains, the physical deviations from the normal among children in elementary and other schools.

Amongst the other subjects of general interest, which will probably be introduced and discussed, are the following:—

In Section A the question of the national physical laboratory, of the central publication of physical papers, of magnetic and other units, and of mechanical connection between ether and matter will probably be raised. It is expected that a discussion on the teaching of physics in schools will take place, as well as a joint discussion with Section C on "Earth Tremors."

Section B will receive communications raising discussion on explosions in coal mines, flame, bacteriology, recent progress in inorganic chemistry, and recent research in organic chemistry, especially in connection with colour and colouring matters. The papers on these subjects are to be classified, and each class will be considered on a special day, of which due notice will be given.

In Section C the presidential address will deal with "The Doctrine of Uniformitarianism as illustrated by recent petrographical research," a subject which Mr. Teall has almost made his own. Papers are expected on East Africa, the new red sandstone of the Midlands, the igneous rocks of Derbyshire, the boulder clays and drifts of the Midlands, the methods and need of teaching geology both as a branch of education and as a valuable training to engineers, miners, and others. Sections C and D will jointly discuss "Fossil and Recent Coral Reefs," both in respect to their origin and in relation to the part which corals have played in the formation of the earth's crust. Sections C and E will also hold a joint meeting for considering the mutual relations of geology and geography.

In Section D Prof. Bohr, of Copenhagen, is expected to communicate the results of researches of great importance on the chemical process of respiration. A discussion will also probably take place on the question how far the fundamental peculiarities of vital processes admit of being explained as merely resulting from the *complication* of the chemical and physical processes of which they consist. It is expected that other moot questions of fundamental importance in biology will also be brought under discussion.

The President of Section E will treat in his address of the Polar Basin, laying stress on some generally forgotten facts and summarising our knowledge of the margin of the Arctic Sea. Mr. W. M. Conway will give an account of his mountaineering experiences in the Karakorum Range. Messrs. Bruce, Burn-Murdoch, and Donald will describe with photographs and paintings the scientific results of a recent sealing expedition to Antarctic waters. Mr. Guy Boothby will describe his journey across Australia from north to south. There will also be papers on the influence of their geographical surroundings upon the people of Northern India, by Mr. E. Henwood, and a similar paper on the Congo Basin by Mr. Herbert Ward. Mr. H. R. Mill will describe the physical geography of the Clyde sea area, and the bathymetrical survey of the English lakes, and Mr. B. V. Darbishire will contribute a paper on some conditions of cartographic representation of distributions.

In Section F the subject of the presidential address will be "The Reaction in favour of the Classical Political Economy." Papers are expected to be read for discussion on the monetary situation by Profs. Foxwell and Cunningham, on agricultural depression by Messrs. H. H. Scott and L. L. Price, on corn averages by Mr. R. Hooker, on Australian banking by Dr. C. Gairdner, on Poor Laws by Dr. F. Wilkinson, on industrial arbitration by Mr. D. Schloss, on the employment of the unemployed, on local industries and the history of Nottingham lace by Mr. Frith and others.

The arrangements for Section G have not been received as yet, but the many promises received from eminent English and foreign engineers to attend the meeting leaves no doubt that the proceedings of this Section will be of unusual interest.

In Section H the subject of the presidential address will be one special phase of man's development. The papers and discussions in this section, always of a diversified and popular character, promise to be of more than usual interest this year. Dr. Hans Hildebrand, Royal Antiquary of Sweden, contributes a paper on "Anglo-Saxon remains, and the coeval ones in Scandinavia," and it is proposed to make his communication the basis of a general discussion, chiefly with the view of defining the special characteristics of Anglo-Saxon remains in this country as distinct from those of Celtic and Scandinavian origin. Another subject, also full of interest and even novelty to English archæologists, is the recently discovered prehistoric lake or marsh village near Glastonbury, which is to be brought before the section by its discoverer, Mr. Arthur Bulleid. As the buried ruins of this village are now being excavated on a larger scale than during the previous summer, it is expected that the amount of industrial remains, already of much archæological value, will be greatly enhanced before the meeting of the Association. It has therefore been suggested that the reading of Mr. Bulleid's report of these researches will be a good opportunity for the eminent archæologists, who have agreed to act as a committee of reference and advice, to discuss the more salient features of this remarkable discovery, and to describe from different standpoints its bearing on the early history of our country. This method of dealing with such a discovery is eminently well adapted both for furthering the objects of the Association and for communicating valuable information to the investigators themselves; and it is earnestly hoped that the committee of experts will find it convenient to be present. Nor do these interesting subjects by any means exhaust the list of the forthcoming materials. Anthropology proper will come largely to the front, and will receive special consideration in the president's opening address to the section, as has been stated above.

Among the more popular scientific communications, the presidential address and the popular evening lectures must take their place. The popular lecturers are Prof. Smithells, who will describe and illustrate his recent researches on "Flame;" Prof. Victor Horsley, who will treat of "The Discovery of the Physiology of the Nervous System;" and Prof. Vivian Lewis, who will lecture to the local working-men on "Spontaneous Ignition." In connection with the last announcement it may be noted that the introduction of the working-men's lecture dates from the last meeting of the Association in Nottingham.

It will probably be possible to make a further communication in our next issue, bringing forward the announcement of the principal arrangements for work and entertainment in a state more nearly approaching completeness and finality. FRANK CLOWES.

MAGNETO-OPTIC ROTATION.

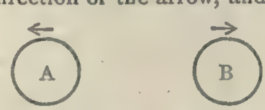
FARADAY'S famous discovery of the rotation of the plane of polarised light by passing the beam through a piece of his heavy glass placed along the lines of force of a magnetic field, was the starting point of the very important department of science now known as electro-optics. From this, as the first observed physical relation between optical and magnetic phenomena, has come the electromagnetic theory of light with all the magnificent researches and discoveries which have marked its experimental verification in recent years. I propose in the present article to give a short account mainly of magneto-optic rotation and the progress which has been made towards its dynamical explanation, followed by a brief discussion of some of the more intimately related phenomena which have been brought to light by recent investigations. It is no part of my plan however to discuss the experimental methods employed in the various researches referred to.

In the first place the magneto-optic relation which Faraday found is to be distinguished from the apparently similar effect which is produced by passing plane polarised light through a plate of quartz cut at right angles to the optic axis, or through a solution of sugar or tartaric acid. In the latter case the turning of the plane of polarisation depends only on the positions of the displaced particles of or in the elastic medium which forms the vehicle of the wave, and not on their motions; in the former the effect is a result of the motions of particles of other matter imbedded in or loading the surrounding ether.

The following illustration is I believe substantially what I have heard given by Lord Kelvin. Imagine two elastic jellies, one bored full of small helical cavities, either all right-handed or all left-handed, and having their axes all in one direction; the other having in it a number of particles endowed with a spinning motion and reacting in consequence of that spinning motion with centrifugal forces against elastic forces of the surrounding medium, and let the direction of axis and of spin be the same in the different cases. The former jelly will transmit circularly polarised waves travelling parallel to the axis of the helix with different velocities according as the helical arrangement of the displaced particles in the wave does or does not agree with the direction of the helical structure, the latter according as the direction of the motion of the particle caused by the wave is with or against the direction of the spin.

This illustration accounts for the essential difference between the results of observation in the two cases. The turning of the plane of polarisation produced by passing the beam through the quartz, or the solution, in one direction, is undone by sending the beam back again; that produced by passing the beam through a proper transparent medium placed along the lines of force in the magnetic field is doubled by reversing the ray after one passage, and returning the light to the side at which it entered.

To understand what takes place in each case we have to consider the nature of a plane polarised ray. According to the electromagnetic theory of light the disturbance in a plane polarized beam consists of an electric displacement in a direction at right angles to the plane of polarisation as defined in the ordinary way by reflection, and a magnetic displacement at right angles to the electric displacement and to the line of propagation, these two actions in a direct unreflected beam having the same phase. It is as yet impossible to say what it is in the ether that dynamically corresponds to these actions; but there can be no doubt that they are phenomena due to motion of some kind of or in the luminiferous ether. In the elastic solid theory of light, which must whether true or false have a certain correspondence with the facts, each part of the ether in a plane polarised beam was supposed to have a vibratory motion in a straight line at right angles to the direction of propagation, the direction of this line being the same along the whole length of the ray. Such a motion as this, it was first shown by Fresnel, may be regarded as the resultant of two oppositely directed circular motions, simultaneously possessed by each moving part of the ether. For consider a motion which would carry a particle round the circle A in a given time T in the direction of the arrow, and another which

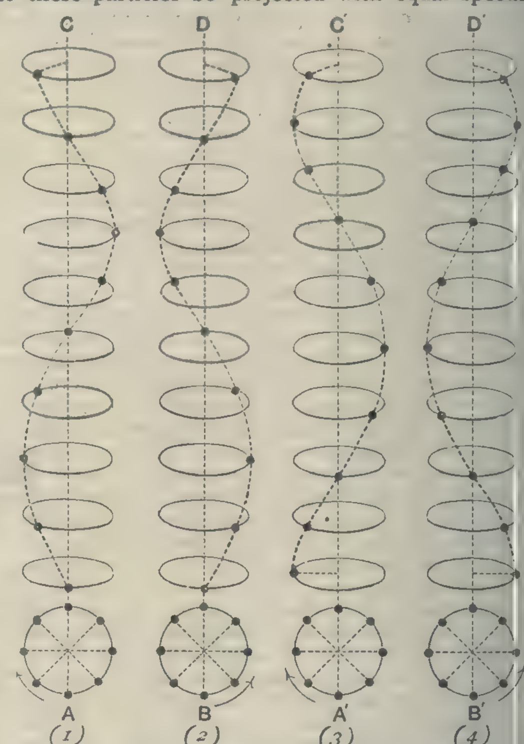


would carry a particle round the equal circle B in the same time in the opposite direction. Imagine two distinct particles to move with equal uniform speeds round the two circles, and suppose that both particles are at the top or at the bottom of their circular orbits at the same time. It is clear that at any given instant both are moving up or both moving down and at the same speed, while when one is moving from right to left the other is moving from left to right with the same speed, and *vice versâ*. Therefore if we conceive these motions united in one particle, the up and down velocities will be simply added together, the right and left motions will cancel one another. Thus the particle will have a simple vibratory motion in a vertical line in the period of the circular motions and with an amplitude of twice the radii of either circle.

Further it is to be noticed that the acceleration of the particle describing this rectilinear motion is the resultant of the accelerations of the particles in the two circular motions and that therefore the force required to maintain the simple harmonic motion is at each instant the resultant of the forces which would have acted on the particles in the circular motions when in the corresponding positions.

Thus the rectilinear vibration of a particle in the luminiferous medium may be regarded as compounded of two circular motions, and the particle as subject to a force compounded of the corresponding forces; and the same may be conceived of each moving particle in the wave.

Now to conceive of the motion in a beam of circularly polarised light and the relative positions of the disturbed particles, let a series of particles initially in a straight line along the direction of propagation be displaced into a helix along that line as represented in the diagram. Let these particles be projected with equal speeds in



the same direction tangential to the surface of the cylinder in which the helix lies, and at right angles to the axis; and further let them be constrained ever after to move with uniform speed in circles round the cylindrical surface. Clearly the helical arrangement will move onward along the cylinder—a circularly polarised wave will be propagated. The helical arrangement, that is the wave, is propagated in one direction or the other, for a given direction of the circular motions according as the helix is right or left-handed, or for the same direction of the helical arrangement according to the direction of the circular motion. Thus the direction of propagation is unchanged if both direction of helix and direction of motion is reversed. All this can be easily made out from diagrams (1), (2) of the figure above. Diagram (1) shows part of a left-handed helical arrangement of particles; (2) part of a right-handed one. Both illustrate the arrangement of particles, originally in a straight line, when disturbed by the passage of a circularly polarised beam. By supposing the particles to have the circular motions indicated below the diagrams, the propagation of the wave can be studied.

It follows therefore that if two such motions co-exist in the same particle both waves will travel in the same direction through the medium. If they travel with the same speed the resulting rectilinear motion of each particle will be the same all along the wave, but if they travel with unequal speeds the direction of this motion will turn round as the wave advances in the direction of the motion of the particles in the more quickly travelling wave, generating if the speeds are constant, the surface of a screw.

To constrain the particles to maintain the circular motions forces must be applied towards the centre of the orbit in each case. The reactions of the particles against these motions are what are properly called the centrifugal forces of the particles. But the different particles are connected by the elastic medium and the required centreward forces are supplied by its rigidity. Thus for given displacements produced by the beam entering the medium the forces due to the medium will be different if the rigidity is less for, say, a left-handed helical distortion than for a right-handed one, and the latter distortion will be propagated with the greater speed.

Now let the wave be reflected after passage, and let the direction of motion of each vibrating particle be reversed in the act of reflection. The direction of the helical arrangement will remain unchanged in each case. The wave which travelled the faster when direct will again do so, but the direction of motion being reversed the direction of motion in the plane polarised beam will turn round in the opposite direction as the wave moves forward, thus undoing the previous turning.

The same thing it is easy to see will take place if the reflection takes place without reversal of motion as at the surface of a rarer medium. In this case the helical arrangement which was left-handed becomes right-handed, and *vice versâ* after reflection. The arrangement which lagged behind before now that is reversed travels the faster and the line of resultant vibration again turns round, but in the direction of the circular motion in that circularly polarised wave which now moves the faster, that is in the opposite direction to that in which it moved before. Diagrams (3) and (4) of the figure show the configurations of parts of (1) and (2) after having been thus reflected.

Now consider the other case. It is observed, we shall suppose, that the right-handed circular ray travels faster than the other, and that whether direct or reversed. As before, the elastic action of the medium on the moving particles can depend only on the displacements of the particles in the helical displacement, and in the absence of any structural peculiarity to produce a difference must react in the same degree on the particles in both circular waves. Thus the centrifugal force reactions being the same for both waves, and the velocity of transmission being different, the luminiferous motions must be unequal, and such that compounded with a motion existing in the medium two motions are produced which exert equal centrifugal force reactions, balancing the equal elastic forces applied in consequence of the equal helical displacements.

According to this theory, which is due to Lord Kelvin, there exists in the medium a motion capable of being compounded with the luminiferous motion of either circularly polarised beam which is therefore a component only of the whole rotational motion. In the passage in which this dynamical explanation is put forward Lord Kelvin goes on to say,

"I think it is not only impossible to conceive any other than this dynamical explanation of the fact that circularly polarised light transmitted through magnetised glass parallel to the lines of magnetising force, with the same quality, right-handed always, or left-handed always, is propagated at different rates according as its course is in the direction or is contrary to the direction in which a north magnetic pole is drawn; but I believe it can be demonstrated that no other explanation of that fact is possible. Hence it appears that Faraday's optical discovery affords a demonstration of the reality of Ampère's explanation of the ultimate nature of magnetism."

A number of interesting conclusions seem to follow from this theory. In the first place the turning effect is not found to any sensible extent unless there is matter of some kind, magnetic or diamagnetic, present in the field. Hence the theory does not point to rotation of the parts of the ether but only to rotational motion of other matter imbedded in it and reacting on the ether in consequence of that motion.

Further, the explanation seems to decide against that view of diamagnetism which regards it as a differential effect due to the greater magnetisation of the surrounding medium. The rotation of the plane of polarisation is found in both paramagnetic and diamagnetic substances, but for the same direction of magnetic field is opposite in the two cases. This points to opposite rotations of the matter in the field according as it is paramagnetised or diamagnetised.

In all ordinary transparent substances which have been experimented on the effect has been found to be small. This of course was what was to be expected from the small amount of magnetisation (or diamagnetisation) produced in such substances even by very powerful fields. As a rule the substances are diamagnetic and give rotation of the plane of polarisation varying directly as the intensity of the magnetic field in which the substance is placed, and directly as the thickness of the medium through which the light is passed. It has been found however by Kundt that the turning produced by passing the light through a thin film of iron or cobalt is very great, a result which forcibly recalls the idea suggested by Lord Kelvin in the paper quoted above, that the moment of momentum of the matter in unit of volume of the magnetised substance might be the proper dynamical measure of the intensity of magnetisation.

Another result found both for magneto-optic rotation and for the turning produced by substances of helical structure is that the effect is greatest for the more refrangible rays of the spectrum, in fact is nearly inversely proportional to the square of the wave length of the light. This is of great importance in connection with the remarkable theory of the production of magneto-optic rotation in a medium having imbedded a large number of very small gyrostats which has been given by Lord Kelvin. In a continuation of the present article I shall endeavour to give a short account of the behaviour of such a medium when subjected to the disturbance due to the passage through it of a beam of plane polarised light. In connection with this theory the fact observed by H. Becquerel, Kundt and others that magneto-optic rotation is produced also in gases is of great interest.

Absolute measurements made by Lord Rayleigh give for bisulphide of carbon ·042 of a minute of angle for the turning of the plane of polarisation of sodium light in passing through a stratum 1 centimetre thick in a field of 1 C.G.S. unit of intensity the temperature being 18° C. A knowledge of this quantity (which is called Verdet's constant for bisulphide of carbon) enables the turning in other substances produced by a given field to be inferred by experiments of comparison. Further the intensities of magnetic fields can be inferred from observed amounts of turning produced by the passage of light through a column of measured length of any substance for which the constant has been determined.

In a succeeding article an attempt will be made to discuss with as little as possible of the aid of technical mathematics the propagation of plane polarised light in a gyrostatically loaded transparent medium, the "Hall effect" which, existing in a transparent dielectric, would there produce magneto-optic rotation, and to indicate shortly some of the bearings of magneto-optic phenomena generally on the electromagnetic theory of light.

ANDREW GRAY.

THE EARTHQUAKE IN BALÚCHISTÁN.

THE *Records of the Geological Survey of India*, May, 1893, contains some notes on the earthquake in Balúchistán on December 20, 1892, by Mr. C. L. Griesbach, one of the Superintendents of the Survey. The paper is illustrated by two photo-etchings, one of which is here reproduced with the description of the occurrence.

The following quotation is from the report of the Executive Engineer of the North-Western Railway at Shalabagh:

"On the 20th December, at 5.40 a.m. (Madras time),[1] this district was visited by a somewhat severe earthquake. It was followed by several lesser shocks, and at Shalabagh[2] they continued at frequent intervals during the day, and have occurred at frequent intervals up to the present date.[3] The exact time of the shock was shown by the stoppage of a pendulum clock in my office.

"*Effects at Sanzal.*[4]—The station building at this place has apparently suffered most, its close proximity to the line of fissure, which runs in a north-east and south-west line about half a mile below the station, being probably the cause. The water tower is standing, but most of the turrets are loose. . . . The oscillation of the ground caused the water to spill out of the iron tanks. . . . The station building, including the station-master's and signaller's quarters and out-houses, are very badly shaken, and will require rebuilding to a considerable extent. The whole of the chimneys have been thrown down.

"Lower down the line the only serious damage to the permanent-way occurred. There is visible at this spot to the eye, for a considerable distance, as far indeed as the eye can reach, a line of division in the soil, and where this intersects the railway at an angle of about 15° or 20°, the metals of the permanent-way were distorted in a most extraordinary way, the pairs of rails in each line immediately above the crack in the ground having suffered most. They were bent into a sinuous curve, which is represented approximately in the accompanying illustration.

View showing distortion of rails caused by earthquake between Sanzal and Old Chaman.

"I have followed the line of fissure in the surface of the ground for a considerable distance on each side of the line, and it extends beyond Old Chaman on the one side for several miles I am told; I myself followed it for one mile beyond Old Chaman, and could then see it extending far into the distance. In the other direction, I am informed by an Achakzai, who had just come from there, it cuts the line of the Khwája Amran range obliquely, and can be traced to the peak of that name, some eighteen miles off.

"There appears to have been a shearing action on the surface of the ground, the line of shear being tangential to the line of cleavage.

"The rails having resisted this motion were crumpled up in consequence. The joints in the rails on each side of the contortion have all been closed up, although of course, originally, clearance for expansion had been left.

"While tracing the crack in the ground through Old Chaman, I found that it crossed all the collecting pipes of the Military Works Department at Old Chaman. Most of these pipes crossed the crack at approximately a right angle and had not suffered, but one $1\frac{1}{2}$ inch pipe which cut it obliquely was pushed up and off the ground and formed a sort of arch over the crack. . . ."

"A week after the earthquake," says Mr. Griesbach, "I visited the Kójak range in company of Mr. Hodson. We first inspected the damage done by the earthquake to the houses and works in the neighbourhood of Shalabagh station at the eastern entrance of the Kójak tunnel. Though there was much mischief done to buildings, &c., not much could be learned from these effects of the earthquake. If the scene of destruction had been in a closely-built town, it might have been possible to detect some method, if I might use the expression, in the damage done, but at Shalabagh the houses are far apart, built on unequal hilly ground, and the workmanship in the buildings, mostly constructed of sun-dried bricks, is also very unequal, so that all one can say is that the shocks of earthquake have affected all the weak points of these buildings, many of which will have to be entirely reconstructed.

[1] At Quetta the shock was felt at 5.46 a.m., the distance from Shalabagh to Quetta being 53 miles in a straight line.

[2] Shalabagh is a station on the Sind-Peshin Railway at the eastern entrance to the Kójak tunnel.

[3] 22nd December.

[4] Sanzal is the first station on the western side of the Kójak tunnel.

"The Kójak tunnel fortunately escaped serious damage, though it is interesting to hear that the water-supply from some springs which issue inside the tunnel and which now escapes in a regular drain from the western (or Chaman side) of the tunnel, was considerably increased after the earthquake shocks.

"The block-house which defends that entrance to the tunnel received some slight damage in the shape of cracks which have appeared in the solid masonry.

"The effects of the earthquake shocks are visible almost all along the made banks on which the permanent-way is laid between the tunnel and Sanzal station. In their case the earthquake acted most beneficially, inasmuch as the artificially built-up material of these banks was well shaken down, and, though the latter had sunk here and there and cracks have appeared in places, their settling down and consolidating was equal to a season's rain, as the engineer of that section reports.

"The real interest of the earthquake, however, centred in the damage done between Sanzal station and Old Chaman.

"The line of railway descends to New Chaman from the Kójak tunnel in several great curves and in zigzag fashion. Sanzal station is situated near the upper margin of a great and rapidly descending glacis, which slopes down from the Kójak range to the great plain in which New Chaman is situated.

"About half a mile west of Sanzal station there is a path which runs from the Khwája Amran peak (8864 feet) in a north-northeast direction along this glacis. It appears that at the immediate foot of the Kójak range a great number of springs rise, close to which of course there is always a certain amount of grazing to be found, and thus this line of springs has been connected by a regular path, made by flocks passing along these patches of pasture-land. The water escaping from these springs has furrowed and denuded the glacis into an infinite number of small channels. Another feature is that the path with its springs and patches of grazing grounds all lie as it were in a natural depression, running parallel with the range of the Kójak itself, whilst immediately to the westward of it the ground of the glacis rises somewhat, before finally descending to the plains. This is well marked near Old Chaman, the foot of which is built on this rising ground.

"About seven to eight miles south of Old Chaman this insignificant rise of ground becomes an auxiliary range of hills, which runs west and parallel with the Kójak range towards the Khwája Amran peak itself.

"I expect to have further opportunities of geologically examining this ground when the weather will permit in the spring; until then I will only state my belief that the present path which connects the springs described indicates, as near as can be, the existence of an old fault-line. At the present time I have no further proof for it than this, that as far as I have been able to ascertain during this hurried visit, the line of path is, roughly speaking, also a geological boundary between the slaty formation of the Kójak and a grey earthy limestone, the latter of which is very probably of upper cretaceous or lower eocene age; this boundary being here suspiciously abnormal in appearance. The springs which rise along it tend further to the opinion that they appear along a line of dislocation, which view is further strengthened by the fact that in the neighbourhood of the springs not only a kind of travertine is visible, but a curious breccia, consisting of debris of both the limestone and the slates of the Kójak and cemented by calcareous rock, is *in situ* and in strong force all along the line of path, but not off it, which breccia I now look upon as a fault-rock. The glacis itself is chiefly made up of recent deposits, fans from the range above, but I hope to discover a more exposed section further south, where the structure of this dislocation, if it is one, will be clearly demonstrated. Finally, but not least, the fault seems to be proved by the earthquake itself, which has originated in a further, though slight, dislocation along a line which exactly and absolutely coincides with the present path connecting the numerous springs.

"In my theory explanatory of this earthquake, I therefore start with the assumption that an old line of fault exists, which runs more or less parallel with the Kójak range itself. In a mountain range entirely formed by flexures, which chiefly correspond to the strike of the range itself, such faults usually exist on a large scale. The lateral pressure which caused the folding of the strata in such cases frequently results in one or several systems of dislocations, as we may observe in numerous instances within folded mountain ranges. . . ."

"From the foregoing it would appear that the process of contracting and folding, with resultant dislocations, of this area in Balúchistán, is still proceeding. At some previous date in the history of the Khwája Amran Mountain range this process of compression, as it must have been, has led to the formation of the line of fault conjectured in these notes; the process, from whatever cause, is still active, and the tension having become too great has further resulted in a slight increase to the amount of dislocation already in existence. The two areas adjoining the fissure have moved about eight inches vertically and a couple or more feet horizontally from each other, which sudden establishment of a temporary equilibrium in this tension is no doubt quite sufficient to account for the vibration of the ground to a considerable distance, which vibration is commonly called an earthquake.

"I need scarcely say that there is no indication of any kind which would point to the existence of volcanic activity at, or anywhere near, the area affected by this earthquake; I mention this only, because it was also in this case, as in other instances elsewhere, the popular theory advanced by many of those who personally experienced the alarming symptoms of this perfectly natural phenomenon."

SCIENCE IN THE MAGAZINES.

OF the August magazines the strongest in articles of scientific interest is the *Fortnightly Review*. Under the somewhat misleading title "The Wanderings of the North Pole" Sir Robert Ball contributes a rather diffuse article descriptive of the variations of latitude; adopting Mr. Chandler's conclusion that the earth's instantaneous axis of rotation revolves about that of maximum moment of inertia, with a radius of thirty feet, measured at the earth's surface, in a period of 427 days. This result is expressed by Sir Robert Ball in the following language:—

In that palæocrystic ocean which Arctic travellers have described, where the masses of ice lie heaped together in the wildest confusion, lies this point which is the object of so much speculation. Let us think of this tract, or a portion of it, to be levelled to a plain, and at a particular centre let a circle be drawn, the radius of which is about thirty feet; it is in the circumference of this circle that the Pole of the earth is constantly to be found. In fact, if at different times, month after month and year after year, the position of the Pole was ascertained as the extremity of that tube from which an eye placed at the centre of the earth would be able to see the Pole of the heavens, and if the successive positions of this Pole were marked by pegs driven into the ground, then the several positions in which the Pole would be found must necessarily trace out the circumference of the circle that has been thus described. The period in which each revolution of the Pole around the circle takes place is about 427 days; the result, therefore, of these investigations shows, when the observations are accurate, that the North Pole of the earth is not, as has been so long supposed, a fixed point, but that it revolves around in the earth, accomplishing each revolution in about two months more than the period that the earth requires for the performanee of each revolution around the sun.

"What use has a serpent for its tongue?" is a question asked by Ruskin of 'scientific people,' "since it neither works it to talk with nor hiss with, nor, as far as I know, to lick with, and, least of all, to sting with, and yet, to the people who do not know the creatures, this little vibrating forked thread, flicked out of its mouth and back again as quick as lightning, is the most striking part of the beast." Mr. W. H. Hudson furnishes an answer to the question. He remarks: "So far from being silent on the subject, as Ruskin imagined, the 'scientific people' have found out or invented a variety of uses for the serpent's tongue. By turns it has been spoken of as an insect-catching organ, a decoy, a tactile organ, and, in some mysterious way, an organ of intelligence. And, after all, it is none of these things, and the way is still open for fresh speculation." Mr. Hudson puts forward the idea that the snake uses its tongue to concentrate the attention of an intended victim upon its head while its body is being trailed forward to effect the capture. We quote from his article:—

In most cases the movement probably would be detected but for the tongue, which attracts the eye by its eccentric motions, its sudden successive appearances and disappearances; watching the tongue, the long, sinuous body slowly gliding over the intervening space would not be observed; only the statuesque raised head and neck would be visible, and these would appear not to move. The snake's action in such a case would resemble the photographer's trick to make a restive child sit still, while its picture is being taken, by directing its attention to some curious object, or by causing a pocket-handkerchief to flutter above the camera.

Snakes have been observed to steal upon their victims in this quiet, subtle manner; the victim, bird or lizard, has been observed to continue motionless in a watchful attitude, as if ready to dart away, but still attentively regarding the gradually-approaching head and flickering tongue; and, in the end, by a sudden, quick-darting motion on the part of the snake, the capture has been effected. . . .

It is not here maintained that the tongue is everything, nor that it is the principal agent in fascination, but only that it is a necessary part of the creature, and of the creature's strangeness, which is able to produce so great and wonderful an effect. The long, limbless body, lithely and mysteriously gliding on the surface; the glittering scales and curious mottlings, bright or lurid; the statuesque, arrowy head, sharp-cut and immovable; the round lidless eyes, fixed and brilliant; and the long, bifurcated tongue, shining black or crimson, with its fantastic flickering play before the close-shut, lipless mouth—that is the serpent, and probably no single detail in the fateful creature's appearance could be omitted and the effect of its presence on other animals be the same.

In an article on "The Limits of Animal Intelligence," Prof. C. Lloyd Morgan gives an interesting account of some experiments and observations he has recently made on young chicks, with a view of determining the difference between intelligence and instinct. He expresses the distinction between the two as follows:—

Intelligence is the faculty by which, through experience and association, activities are adapted to, or, more strictly, moulded by, new ciccumstances; while reason is the faculty which has its inception in the true grasping of relationships as such. Intelligence is ever on the watch for fortunate variations of activity and happy hits of motor response; it feels that they are suitable, though it knows not how and why, and controls future activities in their direction. It proceeds by trial and error, and selects the successes from among the failures. Reason explains the suitability; it shows wherein lies the success or the error, and adapts conduct through a clear perception of the relationships involved. Individual experience, association, and imitation are the main factors of intelligence; explanation and intentional adaptation are the goal of reason.

Incidentally I have expressed my opinion that, in the activities of the higher animals, marvellously intelligent as they often are, there is no evidence of that true perception of relationships which is essential to reason. But this is merely an opinion, and nos a settled conviction. I shall not be the least ashamed of myself if I change this view before the close of the present year. And the distinction between intelligence and reason will remain precisely the same if animals are proved to be rational beings the day after to-morrow. For the distinction holds good between human intelligence and human reason, just as much as between animal intelligence and the possible reason of animals. It is no line of division which separates animals from men; but a distinction between faculties, one of which, at least (and perhaps both, though this I doubt), is common to animals and men.

The *New Review* contains an article by Prof. Ludwig Büchner on "The Brain of Women." It is well known that the average size of the female brain is considerably less than that of the male. Further, up to the present nothing has been found to justify the assumption that there is anything in the inner formation of the brain to make good its deficiency in size as compared to the male. This Prof. Büchner holds to be due to differences of development.

If we consider that for thousands of years woman, by reason of her subordinate social position, has received a different education from her male partner, and that her training has led her in quite another direction to his; that her horizon has been a more limited one, and moreover that every encouragement has been given to the play of her emotions at the expense of the activity of her intellect; and finally that this state of affairs has lasted from generation to generation, through mother to daughter, then, I say, that from a physiological standpoint there should be no cause for surprise that as a result woman should differ from man, that her brain should be inferior to his, or at any rate should have developed on different lines, or, as we have been saying, that the fore part of her brain should be found to be proportionately less and the hind part proportionately greater than that of man.

Mr. Thomas J. Mays writes in the *Century* on "Breathing Movements as a Cure." The evidence he offers indicates that "proper development and expansion of the lungs by means of well-regulated breathing must be regarded as of the greatest value in the prevention and in the treatment of pulmonary consumption."

"Fin de Siècle Medicine" is the title of an article by Dr. A. Simons Eccles in the *National Review*. After animadverting upon "the deficiency of muscular activity as a fruitful source of maladies resulting from the want of combustion and elimination of material used up or vitiated by the disproportionate action of other organs and tissues," Dr. Eccles describes the investigations that have recently been carried out in France and Russia as to the action of certain organic liquids in curing or modifying disease. Writing on "Electricity and Life" in the *Humanitarian*, Mr. H. Newman Lawrence comes to the following conclusions:—

(1) All the thousand and one changes which take place in the structure of the living body, be they due to the never-ceasing and involuntary process of metabolism, or to the exercise of function, or to the effort of will, partake of the nature of chemical change.

(2) All chemical changes are accompanied by electrical manifestations.

(3) Without chemical change and interchange, life does not appear to exist.

(4) Therefore, life is always accompanied by the generation of electricity.

Electrical energy, however, is not the immediate source of the vitality of the body.

Mr. C. T. Buckland contributes an excellent anecdotal article on "Leopards" to *Longman's Magazine*. Hitherto the beast has occupied only a comparatively small space in the popular literature of natural history, and this fact makes Mr. Buckland's experiences doubly interesting. Under the title "Birds of a Feather," Mr. F. A. Fulcher describes in the *Sunday Magazine* the flocking and migration of birds. Dr. J. G. McPherson gives a popular description in *Good Words* of Mr. John Aitken's fog-counter and the results that have been obtained with it. Finally, Miss Agnes Giberne expatiates upon celestial photography and spectroscopy in the *Monthly Packet*. The article is in continuation of an easily-worded series she is contributing under the title of "Sun-rays and Star-beams."

MARIÉ-DAVY.

DR. G. H. MARIÉ-DAVY, who died at Clamecy on July 16, distinguished himself in various branches of physical science. Astronomy, electricity, general physics, and meteorology, all occupied his attention from time to time, and to all of these branches of knowledge he made important contributions. Born at Clamecy in 1820, Marié-Davy entered the Higher Grade Normal School in 1840. Five years later he was appointed to the Chair of Physics at the Montpellier Faculty of Sciences, and also to the Professorship of Medicine. In 1862 Marié-Davy began his connection with the Paris Observatory. At first he had charge of the terrestrial magnetism service, but in 1863 he became the head of the international meteorological department that he had organised. While occupying this position he published a large number of meteorological memoirs and initiated the periodic distribution of reports and bulletins. He devoted himself chiefly to the study of the atmosphere and its changes, with special reference to the bearing of such matters upon agriculture and hygiene. In 1857 Marié-Davy invented a mercurous sulphate battery which was adopted by the French telegraph authorities, and also by some of the services in other countries. About this time he contributed numerous papers on statical, dynamical, and physiological electricity to various scientific societies and journals. During the revolution of 1870 he left the Paris Observatory and accepted a Professorship at the Polytechnic School—a post that he retained until the return of the Government to Paris. In 1887 he was nominated honorary director of Montsouris Observatory. Marié-Davy was a doctor of medicine and a doctor of physical and mathematical science. Among other honours he was a corresponding member of the Bureau des Longitudes, and an honorary president of the Société d'Hygiene. He was made a Chevalier of the Legion of Honour in 1877, and possessed the Brazilian Order of the Rose, as well as a number of other orders and dignities. The many and varied researches carried on by him, alone and in collaboration with other workers, testify to his greatness. He had a keen sense of right, and dared to give his opinion even when his material welfare was likely to be injuriously affected by so doing. A life so rich in results and void of dissimulation is one well worthy of being imitated.

NOTES.

M. PASTEUR has been elected an honorary member of the Vienna Academy of Sciences.

ON August 4, at about 6.45 in the evening, a distinct earthquake tremor was felt in Leicester and the neighbourhood. The wave passed from about south-west to north-east, and produced the maximum effect in Charnwood Forest. It is reported that the shaking lasted for about five seconds, during which a loud rumbling noise was heard.

A REUTER'S telegram from Vienna reports that a disastrous cloudburst occurred in Middle Styria on August 5. A number of houses were wrecked and several persons lost their lives. Two railway bridges were thrown down on the Grazkoeflach Railway. At about half-past ten in the morning of August 8 two shocks of earthquake were felt in the Mur Valley. The tremors travelled from north to south.

A SINGULAR occurrence has recently been reported from Gamlingay, Cambridgeshire. What appeared to be a dense cloud was observed, but to the astonishment of the villagers the cloud suddenly broke up and showered myriads of ants and flies upon them. So numerous were the insects that they almost covered the ground like a carpet.

THE southern counties are suffering from a plague of wasps. Judging from the correspondence in the newspapers, the insect has been unusually abundant, and has done a large amount of damage in certain districts. At Heathfield, Sussex, more than a thousand nests have been destroyed this summer, and the work of destruction is still going on.

A GOLD medal of the value of 1000 Italian lire is offered by the Royal Academy of Science of the Institute of Bologna, to the author of the best memoir describing a new and efficacious system, or a new apparatus, for preventing or extinguishing fires. The memoir may be written in Italian, Latin, or French, and must be sent in before May 7, 1894.

THE Report of the Postal and Telegraph Conference held in Brisbane in March last has just reached us. At one of the meetings Sir Charles Todd strongly urged the desirability of adopting a uniform method of reckoning time, and after a short discussion the following resolution was passed:—"That it is desirable in the public interests that the hour zone system should be adopted in a modified form, so that there should be one time throughout Australia, viz. that of the 135th meridian or nine hours east of Greenwich."

MR. EDWIN E. HOWELL describes in *Science* a meteorite observed to fall on May 26, 1893. The meteorite entered the ground to a depth of about three feet at an angle of 58° with the horizon. It is an aërolite of very pronounced chondritic structure, and has the usual black glazed appearance. The weight of the mass is 22½ pounds, and dimensions 6 × 7 × 9½ inches Mr. Howell proposes to give it the name of Beaver Creek, from the stream by the banks of which it fell.

THE *Reale Accademia dei Lincei* has issued a circular in which is given a list of the published papers of the late Prof. E. Betti. In honour of his memory it has been decided to collect and publish the whole of his scientific works, with an account of his life, written by the president of the Academy, Prof. F. Brioschi. In order that the collection may be as complete as possible, the circular asks all who have any unpublished letters of the famous geometrician, or a knowledge of works not included in the list, to communicate with Signore V. Cerruti, R. Accademia dei Lincei, Roma.

THE Society for Promoting Agricultural Science in Vienna will hold an international exhibition between April 20 and June 10, 1894. The exhibition will include specimens of economical food for the people, army supplies, appliances for saving life, means of transport, and sport in all its branches. This exhibition is being promoted by the Archduke Francis Ferdinand. Detailed information on the subject can be obtained from the Consul-General for Austria-Hungary, 11, Queen Victoria Street.

THE Board of Agriculture have been authorised by the Treasury to make arrangements, by way of experiment, for the transmission by telegraph of the weather forecasts, issued each afternoon by the Meteorological Council, to the telegraph offices in the rural districts of two typical counties, for exhibition in the office windows. The experiment will extend over the months of

August and September, should harvest operations continue so long, and Essex and Northumberland are the counties selected for the purpose. The measure of success which the forecasts now obtain is such as to lead the Board to the conclusion that the information thus made available will be of practicable value to agriculturists in making their arrangements for the following day.

SHARP thunderstorms occurred at several places in the south and east of England on Friday and Saturday last, accompanied by heavy rain or hail. In the eastern and northern parts of the kingdom the rainfall has been exceptionally heavy. At York the aggregate amount for the week ended the 5th inst. was 1·6 inch, while at Yarmouth it reached two inches, or nearly the average amount for the month of August.

THE question as to whether the term "perennial spring" is applicable to the climate of Quito, as it is claimed by many explorers of the equatorial city, is discussed by Dr. J. Hann in the *Zeitschrift der Gesellschaft für Erdkunde*. He comes to the conclusion that the term does indeed convey a fair idea of the climatic conditions of the place. Not only does the mean temperature and its range of diurnal variations resemble that of our May, but also the changeable weather, with its afternoon thunderstorms, rains and hailshowers, recalls our spring months. It is possible that the contrast between the cool mornings and evenings may be felt more severely in the capital of Ecuador than with us, on account of the greater power of the vertical rays of the sun, but the variability of the mean temperature is, on the other hand, much smaller than in our latitudes. The influence of the weather upon health is very much the same as that of our springs, attacking, as it does, all the mucous membranes of the unwary traveller. It is a question whether a perennial spring is as much of a blessing as the poets would have us believe. The charm of spring lies in the reawakening of life after the torpor of the winter, and where this contrast is wanting, the greatest part of the charm disappears.

A METEOROLOGICAL Society has recently been established at Zi-ka-Wei, near Shanghai, under the presidency of the Rev. S. Chevalier, S.J., and has issued its first report for the year 1892. A good stock of self-registering barometers has been purchased by the Zi-ka-Wei observatory, and distributed among the members of the Society who were able to make use of them. The report contains a brief account of the principal typhoons of the year 1892, accompanied by a map showing their paths, and also an interesting article upon the fogs along the northern coast of China, based upon the observations made at several stations of the Imperial Maritime Customs during the years 1889-91. The discussion shows that from September to November the coast is remarkably free from fog, but that from March to July fogs are very frequent either at the Shan-tung promontory or near the estuary of the Yang-tse-kiang. They are most frequent in the early morning, by far the greatest number being observed before 9 a.m. The conditions most favourable to their formation occur with a low and still falling barometer.

Science contains an interesting account by Mr. E. H. S. Bailey of the effects of a cyclone that passed near Williamston, Kansas, on June 21. At one point, where the track of the cyclone was about six hundred yards wide, elm and walnut trees two or three feet in diameter were torn up or wrenched off fifteen or twenty feet from the ground. The storm travelled eastward, and the debris was distributed round its centre in the manner that usually characterises cyclonic movements. Barbed wire fencing and telephone wires were lifted into tree-tops about fifty feet north of their original position. Heavy farm wagons were utterly destroyed, and spokes were broken off near the hub and carried to a distance of quite half a mile. But even these are comparatively unimportant items in Mr. Bailey's catalogue of casualties. We learn that gravestones (the size is not stated) were carried three hundred yards, and that chickens were stripped of their feathers and trees of their foliage. The west sides of the trees that stood the storm were much roughened, while the east sides were unchanged, owing doubtless to the fact that clouds of sand and dust accompanied the wind and assisted it in the work of destruction. Just before the storm left the earth's surface its fury was at the highest pitch and the width of its track was least. The length of the track, as shown by the devastation, was about five miles.

WE learn from the Kew *Bulletin* that the fine collection of *Stapelias* made by the late Mr. Thomas Westcombe, of Worcester, has been presented to the Royal Gardens, together with a number of notes, descriptions, and beautifully executed coloured drawings.

THE *Bulletin* of the Royal Gardens, Kew, Nos. 76, 77, contains an elaborate report on the preparation and export of Chinese white wax. The eggs of the *Coccus* which produces the excretions are invariably transported from the district where they are produced to that in which the wax is obtained. The industry appears to be a decaying one.

THE first three parts of vol. iii. of "Indian Museum Notes," published under the authority of the Agricultural department of the Government of India, contains a great mass of information on the causes of the various diseases which affect crops in India, descriptions of noxious insects, &c. It is edited by Mr. E. C. Cotes, Deputy Superintendent of the Indian Museum, who himself contributes a large number of notes. The third part is entirely occupied by a conspectus of the insects which affect crops in India, 240 in number.

IT would appear from researches made by Fromme and Stagnitta-Balistreri that no inconsiderable number of micro-organisms are capable of producing sulphuretted hydrogen. Fromme employed as culture media ordinary nutritive gelatine to which tartrate, acetate, or saccharate of iron had been added, the reaction being exhibited by the varying shades of brown to black produced by the organism's growth. Balistreri (*Archiv f. Hygiene*, vol. xvi.) used broth with and without peptone, and tested for the presence of this gas by the insertion of strips of lead paper. Amongst those organisms which produce sulphuretted hydrogen are the *B. proteus vulgaris*, the typhoid bacillus, *B. coli communis*, bacillus of rabbit septicæmia, the comma bacillus, whilst *B. subtilis*, the anthrax bacillus, *Micrococcus tetragenus*, the diphtheria bacillus yield a negative result. On substituting for beef broth that prepared from veal, horse-flesh, or haddocks, no difference in the behaviour of the organisms investigated was observed. When inoculated into raw eggs, which contain such a large proportion of loosely combined sulphur, the *Proteus vulgaris*, associated with so many processes of decomposition, failed, in spite of abundant growth, to produce any sulphuretted hydrogen. On boiled eggs, however, this microbe produces this gas. These interesting results suggest that the power of evolving sulphuretted hydrogen may be possessed in a latent state by certain bacteria, and that just as particular conditions may stimulate their activity in this direction, other circumstances may act as a deterrent.

THE power of gradually adapting themselves to their surroundings possessed in such a remarkable degree by many micro-organisms, has been studied as regards their susceptibility to various strengths of disinfectants by Kossiakoff, and still more recently by Trambusti (*Lo Sperimentale*, 1892, fasc. i.). Kossiakoff showed that a larger dose of a particular disinfectant was necessary to destroy an organism which had been trained by being subjected to gradually increasing doses of the disinfectant than was required when the organism was submitted to it without any such preparation. Trambusti examined the behaviour of various bacteria in the presence of corrosive sublimate, and found that they exhibited striking differences in their ability to withstand this material. Thus whereas the pneumococcus of Friedländer was trained to survive an addition of 1 : 2000 parts of the sublimate to the culture media, the bacillus of fowl cholera was not able to withstand more than 1 : 30,000. If, however, the pneumococcus were taken straight from a fresh culture without any previous experience of the disinfectant, it succumbed in a solution containing 1 : 15,000 parts. The bacillus of swine plague (Rouget des Porcs) was induced to resist an addition of 1 : 8000 parts, whereas without training 1 : 15,000 parts infallibly destroyed it. As regards the retention of their pathogenic properties amongst those organisms investigated, the bacillus of swine plague was the only instance in which the virulence was diminished during its treatment, an addition of 1 : 20,000 parts of corrosive sublimate rendering it innocuous, although its vitality was not destroyed in the presence of 1 : 8000 parts.

MESSRS. E. AND L. MACH have done a considerable amount of work in connection with the photography of flying bullets, air jets, and sound waves since their last publication on this subject. Some results gleaned from a series of about 1500 negatives have been recently communicated to the Vienna Academy. Sharp images of Mannlicher rifle bullets were obtained of 3·5 cm. diameter. The disturbing electric contacts in the field were dispensed with, as it was found possible to close the spark circuit mechanically by means of the sound wave produced by the bullet itself. A large number of experiments were conducted with the interference refractometer invented by Ludwig Mach, and constructed in a complete form with the aid of the Academy. After some trials they succeeded in producing homogeneous plane-parallel glass plates large enough to obtain an interference field 8 cm. in diameter. If one part of this field is occupied by a projectile, an air jet, or a sound wave passing one of the interfering pencils, the interference bands, usually rectilinear, appear bent in such a manner as to indicate the change of density of air at any point. For the purpose of instantaneous illumination the electric spark was usually employed, but sometimes, especially in cases where a longer illumination was admissible, as in the photography of air jets, blue monochromatic sunlight was substituted.

A SIMPLE instrument for trisecting any given angle, invented by Dr. E. Eckhardt, is described in the *Naturwissenschaftliche Wochenschrift*. A straight rule has a slot running along two-thirds of its length, with a pin capable of moving along it. A bar is attached to this pin, and another bar to a rivet at the inner end of the slot. Both these bars are equal in length to the remaining third of the rule, and their free ends are joined by means of another pin. When it is desired to trisect an angle, the pin moving in the slot is placed at the vertex, and the other pin in one of the sides, a parallel to the other side, being drawn through the point occupied by the pin. A curve is now drawn by means of a pencil attached to the unslotted end of the bar, and the intersection of this curve and the parallel referred to is the point of trisection required. The instrument also gives an easy construction for an angle of 36° and for the performance of the "golden section." It is exhibited at Chicago by "The Prussian Universities."

AT a recent meeting of the Société Française de Physique, M. E. Ducretet described a method he had employed for making high resistances without self-induction, and hence suitable for use with a telephone in Kohlrausch's method of measuring resistances. He uses a zigzag formed on platinised glass very like that, composed of fine platinum wire, used by M. Mergier, and finds that a piece of platinised glass 75 mm. by 110 mm., allows of the construction of resistances varying from 25 to 100,000 ohms. The glass plates are fixed in a glass vessel by means of an insulating cover, and this vessel is filled with purified petroleum, which M. Pellat has shown to be a very good insulator. In this manner all effects due to moisture in the air are removed, while it is easy to measure the temperature. A layer of mercury, of variable thickness, at the bottom of the vessel allows of the resistance being adjusted to any desired value.

WHILE engaged on some measurements on the electrical resistance of the human body M. Mergier was led to the construction of a simple instrument which, while being easily manipulated, should be capable of making such a measurement with accuracy. The instrument consists of two coils of insulated wire, fixed with their planes at right angles to each other, and placed within the field of a strong horse-shoe magnet. These two coils are connected in series with the resistances to be compared, and to the terminals of a battery. Under these circumstances, the position of equilibrium of the coils depends only on the ratio of the resistances of the two branches (coil and added resistance), and is independent of the value of the electromotive force of the battery. The current is led into the coils by three metallic points, placed one vertically above the other, and dipping into mercury cups. The coils are suspended by a silk fibre or from a steel point working in an agate cup. For use with alternating currents the magnet is replaced by two fixed coils, which are also connected to the circuits containing the resistances to be compared.

MESSRS. DEIGHTON, BELL AND CO. have published a second edition of Dr. W. H. Besant's excellent "Treatise on Dynamics."

MESSRS. J AND A. CHURCHILL have issued a little volume entitled "Homburg-Spa: an Introduction to its Waters and their Use," by Dr. Arnold Schetelig.

WE have received a report containing the results of observations made at Magdeburg meteorological observatory during 1891, under the direction of Herr A. W. Grützmacher.

DR. R. W. SHUFELDT, in *The Auk* of July, gives an account of an examination of the trunk skeleton of a hybrid grouse. His observations confirm an opinion expressed some years ago, that of all the North American grouse, the genera *Pediocaetes* and *Tympanuchus* are most nearly related to each other; in fact, so close is the relation, that the species are fertile *inter se*.

BULLETIN 42 of the Purdue University Agricultural Experiment Station contains a paper by Mr. J. C. Arthur on the relation of the number of eyes on the seed tuber of the potato to the crop obtained. The experimental data brought forward indicate that the proper way to cut potatoes for planting is to divide them into pieces of suitable size, without regard to the distribution of the eyes. In other words, the number of eyes per piece is immaterial, so that the weight or size of the piece should be the all-important factor in preparing seed material.

THE annual report of the Royal Botanic Garden, Calcutta, of which Lieut.-Col. G. King, F.R.S., is superintendent, has been issued. From it we learn that all the efforts to introduce the cultivation of the Japanese paper mulberry have failed. As the superintendent points out, this mulberry yields a beautiful fibre, which is naturally so white that it requires very little bleaching, hence it seems a pity that no wealthy landowner has taken up its cultivation on a large scale.

THE administration report of the Central Museum for 1892–93 has been prepared by Dr. H. Warth, officiating superintendent, and recently issued by the Government of Madras. It includes an account of corundum deposits in the Madras Presidency, and one on the phosphatic nodules of the Trichinopoly district. Dr. Warth says that the entire area covered by these nodules is about ten square miles, and that about four thousand tons of nodules are lying more or less loosely on the surface.

THE fourth volume of the Bulletin of the American Museum of Natural History contains a large number of important papers, among which we note one by Prof. H. F. Osborn and Mr. J. L. Wortman on "Fossil Mammals of the Wahsatch and Wind River Beds," and another by Mr. J. A. Allen on "The Geographical Distribution of North American Mammals." Mr. F. M. Chapman contributes an article on birds and mammals observed near Trinidad, Cuba, with some remarks upon the origin of West Indian bird life, and Mr. W. Beutenmüller gives several papers on Lepidoptera.

THE proceedings of the Bristol Naturalists Society for 1892 contains several interesting papers. Among others of general scientific interest we note a paper describing the fish-remains of the lower carboniferous rocks of the Bristol district, by Mr. A. J. Heath and Prof. C. Lloyd Morgan. Mr. Claud Druit gives an account of the Green Woodpecker, and Mr. H. J. Charbonnier contributes some notes on the habits of the larvæ of Gracillaria Syringella. Dr. J. A. Norton writes on the coloration of cuckoo's eggs. We regret to learn from the report that this once flourishing society is declining in numbers.

MESSRS. NEWTON AND CO., Fleet Street, have brought out a new kind of gyroscope top, which should be of interest to students of the dynamics of rotation. In it a shallow bell with heavy rim takes the place of the usual disc. At the inner apex is a point which rests on a steel cup in the top of a firm upright. By means of this support, freedom of motion in different planes is obtained without the use of gimbals. The top can be set spinning by twirling it between the fingers, and, owing to the fine workmanship, it will keep in motion for a considerable time. If any geometrical figure made by bending a piece of stout wire is fixed above the point of support, the upper end of the axis of the top follows the form so long as rotation is obtained, running continuously round it in a very remarkable manner. If the top were intended for a gyroscope, its axis should always remain parallel to itself unless guided in the way described. But this is not the case. The axis slowly gyrates and wobbles as it does so. These motions certainly imitate precession and nutation, but the mode of exemplification may lead beginners to a misconception. There is a possibility of being led away with the idea that the earth's axis changes its direction by itself, whereas it cannot be too strongly insisted upon that the effect is produced by external attraction.

AN important communication upon the production of ozone at high temperatures is contributed by Dr. Brunck, of Freiberg to the current number of the *Berichte*. The very title of the memoir is contrary to all our usually accepted ideas concerning the stability of ozone, but Dr. Brunck advances experimental evidence to show that polymeric oxygen is capable of formation and of subsequent existence for a short time even at temperatures of considerable elevation. It is quite true, as Andrews and Tait long ago pointed out, that at 300° ozone is converted into ordinary oxygen, indeed, Prof. Andrews gave 237° as the temperature of dissociation; but Dr. Brunck shows that the change is by no means instantaneous, and that if the gas is only allowed to remain for a short period of time in the heated vessel, a considerable proportion escapes decomposition. A quantity of oxygen was partially ozonised in the ordinary manner by means of a Siemens tube, and the gases, which contained about five per cent. of ozone, were led very slowly through a combustion tube heated to 350° in an air bath; the issuing gas was found to still contain twenty per cent. of the original quantity of ozone present. Filling the combustion tube with fragments of porcelain did not appear to materially diminish the quantity of ozone escaping dissociation. Dr. Brunck then proceeds to describe several high temperature reactions in which oxygen is liberated to a not inconsiderable extent in the condensed form of ozone. Schönbein some years ago made the remark that the oxygen evolved upon heating certain metallic oxides and peroxides appeared to contain ozone, inasmuch as it rapidly liberated iodine from potassium iodide. This statement, which appears to have been overlooked or mistrusted, is completely confirmed by Dr. Brunck, who shows that oxide of silver evolves as much as five per cent. of its oxygen in the form of ozone.

THE most interesting portion of Dr. Brunck's paper, however, is that in which he adduces experimental evidence that the strongly odourous gas hitherto considered to be chlorine, which is usually admixed to a slight extent with the oxygen prepared by heating a mixture of potassium chlorate and manganese dioxide, is in reality ozone. It is certainly singular that Marignac, on attempting to determine the amount of such admixed so-called chlorine in a strongly odourous specimen of the gas, only obtained three milligrams of silver chloride from fifty grams of potassium chlorate. Dr. Brunck now shows that an aqueous extract of the residue in the flask, after heating the mixture of potassium chlorate and manganese dioxide, always reacts neutral to litmus; whereas if free chlorine were evolved the residue must of necessity be alkaline. Moreover, even after repeated washing of the gas with concentrated solutions of caustic potash, sufficient to remove any free chlorine, the gas still maintains its strong odour, at once forms blue iodide of starch with a starch and potassium iodide paper, and bleaches a moistened litmus paper. Further, upon leading the gas through alcohol, aldehyde is produced, an oxidation which free oxygen alone is incapable of bringing about. The active properties and the odour are, however, completely lost after passage of the gas over a layer of manganese dioxide at the ordinary temperature, as would be the case if ozone were the energetic gas present in the oxygen. The above experiments concerning the comparative stability of ozone for a short time at high temperatures quite account for the formation of ozone when a mixture of potassium chlorate and manganese dioxide is heated. Dr. Brunck finally shows that the amount of ozone produced is considerably augmented by removing the escaping gases more rapidly from the heated mixture by means of a current of air or other inert gas. Pure potassium chlorate appears to yield no ozone upon heating, but a mere trace of impurity, such as potassium chloride or silica, causes more or less of the oxygen to be evolved in the form of ozone. Hence commercial chlorate always yields a small proportion of ozone.

NOTES from the Marine Biological Station, Plymouth.—The floating fauna has now begun to assume its distinctive autumn characters. During the past week there were taken, in addition to the larvæ of *Chætopterus*, *Amphioxus* larvæ, the *Tornaria* larva of *Balanoglossus*, numbers of *Plutei* and some *Bipinnariæ*, larvæ of the Polychæta *Magelona* (very young), *Pectinaria*, and *Polydora*, together with scores of *Pilidium*. Medusæ were very plentiful, especially the Leptomedusæ *Laodice cruciata*, *Obeliæ*, and an unidentified *Irene*-like Phialia, and, among Anthomedusæ, a small Margelid. There were also taken two specimens of a species of *Geryonia*, and several of the amethyst tentacled *Amphinenia Titania* (= *Saphenia dinema* of Forbes). *Noctiluca* has reappeared in small numbers. *Evadne Nordmanni* is extremely plentiful; *Podon* on the other hand is relatively scarce. The following animals are now breeding:—The Cladoceran *Evadne Nordmanni* (most carrying embryoes, some provided with the "winter egg"), and a few Lobsters (*Homarus vulgaris*).

THE additions to the Zoological Society's Gardens during the past week include a Lesser White-nosed Monkey (*Cercopithecus petaurista*) from West Africa, presented by the Rev. W. Meikleham; a Brown Capuchin (*Cebus fatuellus*) from Guiana, presented by Mr. T. Birks; a Rhesus Monkey (*Macacus rhesus*) from India, presented by Dr. G. Lindsay Johnson, F.Z.S.; a Leadbeater's Cockatoo (*Cacatua leadbeateri*) from Australia, presented by Capt. St. G. Ord; an Imperial Eagle (*Aquila imperialis*), two Great Eagle Owls (*Bubo maximus*) European, presented by Mr. Charles Clifton Dicconson, F.Z.S.; a Common Jay (*Garrulus glandarius*) British, two Alligators (*Alligator mississippiensis*) from the Mississippi, presented by Mr. Walter D. Marks; a Yellow-billed Sheathbill (*Chionis alba*) cap. at sea off Staten Island, presented by Capt. E. England; seventeen Guillemots (*Lomvia troile*), two Puffins (*Fratercula arctica*), twelve Kittawakes (*Rissa tridactyla*) British, presented by Mr. Thomas A. Cotton, F.Z.S.; a Cape Crowned Crane (*Balearica chrysopelargus*) from South Africa, presented by Mr. E. S. Spooner; two Peregrine Falcons (*Falco peregrinus*) from Ireland, presented by Capt. R. A. Ogilby, F.Z.S.; a Larger Hill Mynah *Gracula intermedia*) from Northern India, presented by Dr. Best; two Montagu's Harriers (*Circus cineraceus*) European, presented by Lord Lilford, F.Z.S.; ten Slowworms (*Anguis fragilis*) British, presented by Mr. F. A. Leach; a Black Rat (*Mus rattus*) British, presented by Mr. Arch. E. Scott, F.Z.S.; a Brown Capuchin (*Cebus fatuellus*) from Guiana, a Ring-tailed Lemur (*Lemur catta*) from Madagascar, a Ring-tailed Coati (*Nasua rufa*) from South America, deposited; a Yak (*Poephagus grunniens*) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

COMET 1893 (RORDAME-QUÉNISSET).—Herr E. Lamp gives a four-day ephemeris for this comet in *Astronomischen Nachrichten*, No. 3175, as obtained by using the elements he published in a previous number of the same journal:—

12h. Berlin M.T.

1893.	R.A. (app.) h. m. s.	Decl. (app.) ° ′
August 8	12 9 29	+12 28·8
12	12 12 51	11 7·2
16	12 15 38	9 58·7
20	12 18 2	8 59·8

This comet is now rapidly fading, and at the same time becoming very unfavourably situated on account of its rapid southerly motion.

COMET FINLAY 1893.—The following is the current ephemeris for Finlay's comet:—

12h. Paris M.T.

1893	R.A. (app.) h. m. s.	Decl. (app.) ° ′ ″
August 10	5 57 30·2	+23 7 14·3
11	6 1 16·4	9 53·9
12	5 0·6	12 12·3
13	8 42·6	14 10·0
14	12 22·5	15 47·6
15	16 0·3	17 5·8
16	19 35·9	18 5·1
17	6 23 9·3	23 18 46·0

TOTAL SOLAR ECLIPSES.—Under this heading Mr. Turner (*Observatory*, No. 204) says a few words about the results of the late eclipse and also the total eclipse that will occur on August 8, 1896. With regard to the former the observers who went out may be thoroughly congratulated on their performance. The photographs that were taken of the corona are, as Mr. Turner informs us, now in the hands of Mr. Wesley, who will make drawings of them, as he has done in the case of previous eclipses. During his recent visit to England Prof. W. H. Pickering compared the photographs he took with those already mentioned, with the result that many most interesting points have been revealed. Prof. Pickering, it may be remembered, employed one of Dr. Common's 20-inch reflectors of 45-inch focus, and, used slow plates, with the result that he "has got more detail in the inner corona than is shown on the English photographs." Referring to the eclipse of 1896 Mr. Turner points out the importance of making preparations a long time beforehand, in order to eliminate the possibility of hasty arrangements at the last moment. In the case of this eclipse it seems not a bit too early to commence, for, owing to the most favourable position of the central line of totality, it is probable that a host of observers, both professional and amateur, will be able to co-operate in the observations.

The central line cuts through Norway in the north, the east coast being the more favourable both for observation and comfort in travelling. Passing across Nova Zembla the line reaches Japan, and thus, as Mr. Turner says, "another delightful trip is open to any one with plenty of leisure."

The details of the eclipse are as follows:—

	At Varanger Fjord. d. h. m. s.	Nova Zembla. d. h. m. s.	Siberia. River Amur. d. h. m. s.	Japan. I. of Yezo. d. h. m. s.
Eclipse begins Aug.	8 16 59 43	8 18 30 1	9 1 16 13	9 1 55 8
Totality " "	8 17 55 37	8 19 28 59	9 2 27 31	9 3 5 26
Eclipse ends	8 18 55 31	8 20 31 54	9 3 36 54	9 4 13 10
Duration of totality	0 0 1 46	0 0 2 0	0 0 2 46	0 0 2 40
Sun's alt. at totality	15°	22°	46°	43°

THE OBSERVATION OF AURORÆ.—We have previously had occasion to refer to the movement for systematically recording the occurrence of auroræ which has been set on foot by Dr. M. A. Veeder. Public attention has lately been called to the matter by a long article in the *New York Sun* describing the plan of observation and the important results that must follow from its extended adoption. The method of observation is very simple, and requires but little time. Each observer indicates on the blanks supplied for the purpose the presence or absence of the aurora. Whenever the fact has been verified by observation the figures denoting the exact time at which the observation was made are entered in the proper space in the blank. The facts which it is especially desired to learn are the exact times of sudden changes in the brightness of the aurora, the extent of sky which it covers, and its position relative to the true north. In case observations are not made the spaces are simply to be left blank. Each blank sheet prepared in this way covers an entire month, and is arranged so as to enable comparisons to be made at a glance between the records from different stations. Only by the coordination of results uniformly recorded can any definite information be obtained as to the distribution, periodicity, and source of luminosity of auroræ. Dr. Veeder has employed his scheme of observation for some years, and finds that it works satisfactorily. Arrangements have been made for its introduction into the observatories of Archangel, Pawlosk, Ekatrainbourg on the Ural mountains, Irkutsk in Siberia, and at other points. The Director-General of the Italian Meteorological Service has also written expressing approval of the purposes of the research, and promising to aid it in every way possible. American observatories have also taken up the system, and other observations have been provided for on an extensive scale, so interesting and important results may be expected. Those who desire to take part in the work can obtain all information relating to it by application to Dr. Veeder, Lyons, New York.

NEW DETERMINATION OF THE CONSTANT OF UNIVERSAL ATTRACTION.—In a note under this heading on July 27 we gave a list of some of the different values obtained for the density of the earth. The following should be added to make it more complete:—

Jolly and Poynting, by the method of weighing, obtained 5·58 as the value for the mean density.

Wilsing's determinations in 1887 and 1888 gave 5·58 with a very small probable error.

"HIMMEL UND ERDE" FOR AUGUST.—In the current number of this periodical Prof. von Braunmühl contributes the discourse which he delivered before the Mathematical Society at München on "Galileo Galilei." Dr. Wilhelm Meyer continues his series of chapters on the planet Mars, and in this one he is able to reproduce some of the most interesting drawings of Prof. J. M. Schaeberle, made at the Lick Observatory. The discussion deals chiefly with the observations made and the suggestions put forward by such observers as Holden, Schaeberle, Barnard, Pickering, &c. Chapter v., on "The origin of the world according to opinions from the time of Kant up to the present," by Herr Guizel, deals with the process of development of the heavenly bodies, the case of comets receiving the writer's special attention.

Among the notes are found a few words about the sun and magnetic storms, with reference to Lord Kelvin's recent views, types of weather in Australia, driving ice in southern latitudes, and several others.

GEOGRAPHICAL NOTES.

THE question of the death of Emin Pasha is again under discussion. It is one of the most difficult problems associated with Africa to estimate the amount of credence due to native or Arab reports. The dictum that bad news travels fast in Africa has been repeatedly proved, but rumours of the death of every explorer of note who has buried himself for a time in the interior have been so persistent and so often falsified, that hesitation is justified in believing Emin dead. It may very well be that he was killed, as Arab report affirms, in October last, while on his great journey across Africa, by the very route which brought Stanley to his rescue five years ago. But on the other hand, it may very well be that he is pushing on leisurely towards Lake Chad and keeping his movements secret for political purposes.

A NEW field of discussion in geography appears to be about to open if we read literally the title "An Undiscovered Island off the northern coast of Alaska," in the last part of the *National Géographic Magazine*. The existence of an island in 73½° N. and 153½° W., north of Point Barrow, is inferred from some rather vague reports of whalers, and some still vaguer stories of the Alaskan Eskimo. Mr. Marcus Baker, who introduces the new land, believes in it sufficiently to propose the name Keenan Island for it; but General Greely contributes a note to the paper in which he shows good reason for believing that the whalers were mistaken, the Eskimo misunderstood, and the new land non-existent.

THE *Revue de Geographie* commences a series of articles on "Questions Géographiques," with a paper on the gaps in our knowledge regarding the vertical relief of France, by M. A. Thalamas. To fill these he urges the importance of supplementing the ordinary hypsometrical maps by sections, and by a complete series of perspective photographic views taken from characteristic points.

THE Rev. R. P. Ashe, author of the standard work on Uganda, and for many years resident there as a missionary, has returned to this country, bringing much valuable information regarding the geography of Eastern Equatorial Africa, which will doubtless soon be made public.

A NEW Geographical Society has been established at Tunis, having for its special aim the study of that protectorate. Not only geography but history, archæology, anthropology, colonisation, commerce, and "natural science" have places on its programme.

THE INSTITUTION OF MECHANICAL ENGINEERS.

THE Institution of Mechanical Engineers held their annual summer meeting at Middlesborough, under the presidency of Dr. William Anderson, F.R.S., during last week. The meeting commenced on Tuesday, August 1, and lasted until the following Friday. Two sittings were held for the reading of papers, four of which were read and discussed, as follows:—On recent developments in the Cleveland iron and steel industries, by Mr. Jeremiah Head, past president, chairman of the reception committee.—On the Middlesborough salt industry, by Mr. Richard Grigg, of Middlesborough. Communicated through Mr. E. Windsor Richards, vice-president.—On some engineering improvements in the River Tees, by Mr. George Clarke, of Stockton, engineer to the Tees Conservancy Commission. Communicated through Mr. Thomas Wrightson, M.P., chairman of the works committee of the Tees Conservancy Commission.—Description of the electric rock-drilling machinery at the Carlin How Mines in Cleveland, by Mr. A. L. Steavenson, of Durham. Communicated through Sir Lowthian Bell, Bart., F.R.S., past president.

Mr. Head's paper, as its title denotes, was of a very complex nature. The author traces the rise and progress of the iron industry in the Cleveland district, which, before the development of the ironstone in the Cleveland hills, was practically a purely agricultural country. The opening of the Stockton and Darlington Railway inaugurated a new era, which was to dawn over this part of the kingdom, and substituted for the calm frugality of a pastoral calling the grime, smoke, wealth and squalor of a manufacturing industry. John Vaughan was the man who made Middlesborough, and rightly his statue stands in the middle of that unlovely town. He was a typical pioneer, dogged of purpose, shrewd yet kindly. He probably did more towards advancing the commercial supremacy of this country than any six statesmen the century has produced. The first blast furnaces were erected in the Cleveland district by his firm, Bolckow, Vaughan and Co., at Middlesborough, in 1852. These were quickly followed by others at Port Clarence near by. They were erected by Bell Brothers, and Sir Isaac Lowthian Bell, the head of the firm, attended at the meeting and spoke in the discussions on the papers. Although advanced in years he is still a keen man of business and of vigorous intellect; the present Mayor of Middlesborough is his son. After the date we have mentioned Middlesborough grew like a gourd and flourished like a bay-tree. Her prosperity seemed as firmly founded as her gigantic blast furnaces, which were then the wonder of the whole iron-making world; but a greater man than either Vaughan or Bell arose, and with the invention of Henry Bessemer, the iron age gave place to the age of steel. Happily for Middlesborough it is difficult to divert the course of trade although the Cleveland ore is not suitable for steel making; or at any rate, was not until the basic process was introduced years afterwards. Middlesborough is well situated for communication by sea with the continent. The great deposits of hæmatite ore, from which by far the greater part of British steel is made, were discovered at Bilbao, in Spain, and Cleveland set vigorously to work to improve the naturally insignificant stream upon which she is situated. With characteristic northern energy the Tees was transformed from a creek with three and a half feet at low water, spring tides, to an estuary with twenty feet as a minimum depth and thirty-seven feet at high water. The ironmasters of the district, who had become numerous and influential, quickly laid down the necessary plant and machinery for making steel. Unfortunately, in a few instances, but those important ones, the vigorous parent stock was succeeded by a more debased growth and that for a time checked to some extent advance, or at any rate gave other districts an advantage; still the iron industry of Cleveland was so firmly established that it still remains the leading iron-producing district of England. At the present time Middlesborough is suffering, like all other parts of the kingdom, from the dulness of trade. There are more blast furnaces, more converters, more open hearth furnaces, and more steel and iron-producing machinery in the world than the world has call for. The engineer has so multiplied manufacturing facilities that we make more than we want, great as is the demand for iron and steel in modern economy. When process was cheapened by the ingenuity of inventors, those who first took advantage of the new means at their disposal became quickly rich. Investors and speculators crowded on to the field, and before the fact was known the producing power of man in the iron industry had been overdone. Sometimes in those strange fluctuations of trade which are the baneful characteristic of the present day, the demand more nearly reaches the power of supply; then for a few months, on the crest of this wave of inflated prosperity, works are busy and prices high. That lasts but a short time, and during the recent meeting the members of the Institution of Mechanical Engineers had the mournful spectacle presented to them of idle plant and unemployed workpeople, although each works manager put as bold a face as possible on his adversities, and strove to crowd as much work as his order book contained into the one day's visit of the institution.

To return, however, to Mr. Head's paper. We find that in 1872 there were thirty-seven iron works in the north-east district. Twenty-one have since disappeared or are now inoperative; whilst nineteen remain. The figures are delusive, for the size and power of production per works are now far beyond what they were at the earlier date. To show how steel has superseded iron, we find by the paper before us that the trade in iron rails has declined nearly 99% since 1872; whilst other kinds of finished iron have declined to the extent of 36% since the same date. Instead of finished iron absorbing 40% of the Cleveland pig-iron made as in 1872, in 1891 it absorbed only about 23%. The quantity of ore raised in Cleveland in 1872 was about 6,300,000 tons, and the quantity of pig-iron made in the north-east district about 1,920,000 tons. During the year 1891 there were produced in the north-east district 795,487 tons of steel ingots. In the latter year 2,260,000 tons of ores other than Cleveland were smelted and of these about 2,100,000 tons were imported chiefly from Spain. On the whole, there has been produced in this district about 36% more pig-iron than in 1871.

It is rash indeed to prophesy in industrial matters, which are influenced by many complex problems, but it would seem that the great change which is impending over Middlesborough is the adoption of a new process in steel making. To bring ore from Spain—the greater part of which is converted into slag, simply to encumber the ground; whilst a smaller percentage ultimately finds useful application—seems an artificial proceeding. At first it was forced upon English steel-makers, from the fact that our native ores, with few exceptions, are phosphoric and therefore unfit for the pneumatic process of steel-making. Later discoveries have removed this disability and by the basic process phosphorus can be eliminated, and good steel made. The Cleveland district is richer in iron ore of high quality than any other in England, but this ore is not suitable for steel-making by the old acid process. It is therefore the manifest duty of Cleveland to foster and perfect the basic system of steel-making, and so use the phosphoric ores of her native hills. The problem is chiefly a commercial one. Happily the stagnation of trade will quicken the ingenuity and enterprise of steel-makers, and we shall no longer depend so fully on a foreign source for the raw material of the most important industry in the kingdom.

The discussion on Mr. Head's paper turned chiefly on the respective merits of Yorkshire iron and mild steel. Mr. Windsor Richards said that best Yorkshire iron was better than the best mild steel made. The statement is too sweeping, and those who use this material will be more likely to agree with Dr. White, the Director of Naval Construction, who spoke in praise of mild steel, laying emphasis on the lower price it costs compared to Yorkshire iron. Mr. Aspinall, the chief Locomotive Engineer to the Sheffield, Manchester, and Lincoln Railway, and one of the best mechanical engineers in the country, also spoke strongly in favour of steel, traversing Mr. Windsor Richards's statement that the mildest descriptions could not be case-hardened. The subject, however, is somewhat antiquated, and were it not for the high authority of Mr. Windsor Richards, would hardly be worth reopening. The difficulties that stood in the way of steel for engineering purposes have been overcome years ago.

The next paper on the list was a contribution by Mr. Richard Grigg, and dealt with the newest industry of Middlesborough, namely, that of salt manufacture. The late John Vaughan, boring for water, came upon salt, and the result has been that quite a brisk industry has sprung up. At first the wells were made by the diamond drill, but the process was so expensive that the industry would have been strangled in its birth, had it not been that American ingenuity came to its aid. The salt in the Middlesborough district is at a considerable depth below the surface; in some places 1700 feet. The strata that have to be bored through are difficult, and it was thought at one time that the salt was too deep to win with profit. Some shrewd person, who had travelled in Pennsylvania, remembered how the Americans make their oil wells, and the system has been transplanted to Middlesborough, so that in some parts one might also fancy one's self in the neighbourhood of Pittsburg, so closely have the characteristic timber derricks been copied in this heart of the iron country. The chief point of interest raised by Mr. Griggs's paper was whether the brine-pumping is going to lead to subsidence or not. On the other side of our island, in the salt districts of Cheshire, brine-pumping has led to most curious and, to those on the surface, unpleasant results. The houses in Northwich bear evidence of this; the house-line presents most devious and irregular courses; the houses themselves are iron strapped or wooden bound, so that they may be "jacked" to lift them, as the earth upon which they stand subsides, and it is no uncommon thing for a Northwich landlord to be called on to the rescue of his buildings, which are in process of disappearing beneath the surface. In one place a house has so far settled down that what was the first-floor bed-room has become the basement, and the front door has been cut off between the two upstairs bed-room windows. Northwich Bridge has been lifted several times, or it would have been transformed into a dam; whilst large tracts of land have subsided bodily, and in one place there is, or used shortly ago to be, a line of rails which ended abruptly at the edge of a cliff, the remaining part being on a plain beneath. At one time these rails were continuous, and were only broken through subsidence caused by the abstraction of salt beneath. Probably, however, Middlesborough will not be served in this way. The salt there is deeper, and is surmounted by a stratum of rock. As the brine-pumping goes on, and large cavities are formed by the abstraction of salt, the roof of rock is left unsupported. The superincumbent mass of earth may, or may not, break this down. It is hoped that should a fall of the rock take place, the pieces descending will form themselves into a dome shape, and, therefore, be well calculated to resist the weight above. The hope appears too sanguine, for the rock would be more likely to give way over the centre of the cavity than at the sides, where it is nearer the supporting salt not dissolved; indeed, the dome would more likely be an inverted one. In the Cheshire district we believe the subsidences have invariably been of a gradual nature, so that inconvenience rather than danger has been the result. In Middlesborough the results may not be of the same gentle kind. It is true that the cavities are deeper in the earth, and that is an element of safety in one respect, but should the stratum of rock below give way suddenly serious results might follow, especially if some of Middlesborough's ponderous furnaces were above the spot affected. Near Nancy, in France, a subsidence of earth took place which was so sudden that it caused a report which was heard 12 miles away. Middlesborough is pumping salt close to the town, and what is, of course, worse, in the near neighbourhood of the docks. Authorities, however, differ as to what will be the result; time alone will prove; it may be in a manner more convincing than pleasant. Mr. Griggs's paper contains an excellent description of the machinery used, and illustrations of the same were exhibited on the walls of the Town Hall, where the meeting was held.

A paper by Mr. A. L. Steavenson, entitled, "Description of the Electric Rock-Drilling Machinery at the Carlin How Ironstone Mines in Cleveland," was next read. After briefly referring to the various means of drilling holes for blasting purposes, the author proceeded to describe the electric drill. We could not give a description of this without the illustrations which were exhibited on the walls. Mr. Steavenson, who is a mining engineer, has tried all kinds of drilling—hand, compressed air, hydraulic, and petroleum engine, but he gives preference to electricity as a means for transmission of power in this work, although he says that petroleum engines have done good work.

The last paper read at the meeting was a contribution by Mr. George J. Clarke, engineer to the Tees Conservancy. In this he describes briefly some of the works which have been done in making the harbour at Teesmouth and improving the navigation. Dredgers, training-walls, and breakwaters have been combined in this work which has proved of such signal value to the district; in fact they have made its large commerce possible.

During the meeting a number of excursions to various ironworks were made, and members had an opportunity of seeing the colossal proportions to which the machinery for the production of iron and steel has been carried in the present day.

THE WILLIAMS COLLECTION OF MINERALS.

A FEW words relative to the collection of minerals which has just been distributed among various museums by Mr. J. C. Williams, M.P. for the Truro Division of Cornwall, will be of general interest. This collection had been gradually brought together by the father and grandfather of Mr. Williams; it was removed nearly thirty years ago from Scorrier, where Mr. Michael Williams formerly lived, to Caerhays Castle, nine miles from the nearest railway station (St. Austell), and it has since been too remote from the ordinary line of travel to be of easy access to visitors. It was in this collection, while it was still at Scorrier, that my predecessor, Prof. Maskelyne, F.R.S., noticed in 1863 the specimen of connellite from which it seemed to him that the first crystallographic measurements might be obtained: the specimen was presented by Mr. Michael Williams to Mr. Maskelyne for the British Museum, and has ever since been on exhibition in the Gallery. As the crystals were only $\frac{1}{350}$th of an inch in thickness, the determination of their form was a noteworthy piece of scientific work; and it may be observed that the more recent discovery of larger crystals of the same beautiful mineral in another Cornish locality has only served to confirm the remarkable accuracy with which the form of those acicular crystals was then determined.

A short time ago, Mr. J. C. Williams, whose open-handed generosity is well known in Cornwall, perceiving that the continuance of the collection in so isolated a museum as that of Caerhays Castle prevented its utility both to students and the general public, decided to select some of the specimens for preservation in the family, and to present the remainder to public museums. Accordingly, in a courteous letter, he invited me to Caerhays to select any specimens which would be useful in completing the series preserved in the British Museum, and I immediately went down, accompanied by my colleague Mr. Miers, to examine the collection and remove the specimens which should be selected.

The collection, which amounted to about 10,000 specimens, was exhibited in numerous glazed wall-cases and table-cases in a large hall well lighted from the roof. The specimens were from various parts of the world, but as a rule only those of local origin could be of service for an old-established collection like that of London: the Cornish specimens, however, formed a series which, owing to the closing of so many mines and the change of mineral conditions in others, it would be quite impossible to reproduce in the present day: for the acquisition of such specimens the successive owners of the collection, by reason of their interest in Cornish mining enterprise and its products, have had excellent opportunities of which they have not failed to make use. In all, nearly 300 specimens were reserved by Mr. Williams for continued preservation at Caerhays; 510 specimens have been selected for the British Museum; the collection formed by the late Mr. John Taylor (to whom the British Museum was indebted for the donation of some excellent mineral specimens), and acquired at his decease by Mr. Michael Williams, has been given, with the exhibition-cases containing it, to the Camborne Museum; the remaining specimens and exhibition-cases have been divided between the museums of Redruth and Truro.

That the character and extent of the donation to the British Museum may be more readily appreciated by visitors, the selected specimens have been arranged in four window-cases of the Mineral Gallery, and will be exhibited together for a year or two before their distribution through the main collection. Special attention may be directed to two specimens of blende (sulphide of zinc) which for size and excellence are superior to any yet heard of, and in colour somewhat resemble those from Hungary. A remarkable specimen presenting crystals which are of an emerald-green colour and of unusual form, has been examined by Mr. Miers in conjunction with Mr. Prior, and will shortly be described by the former. He finds the crystals to be identical with spangolite (sulphate and chloride of copper and aluminium); of this species, described by Mr. Penfield three years ago, only one other specimen, found and preserved in the United States, is known to exist. There is a fine suite of crystallised specimens of cassiterite (oxide of tin). Special mention, too, should be made of the specimens of redruthite (sulphide of copper), the large series of specimens of chalcophyllite, clinoclase, and olivenite (arsenates of copper), libethenite (phosphate of copper), liroconite (phosphate of copper and aluminium), cupro-uranite (phosphate of copper and uranium), pyromorphite (phosphate and chloride of lead), cerussite (carbonate of lead), chalybite (carbonate of iron), and fluor.

The thanks of Cornish and London students are due to Mr. J. C. Williams for the generosity and self-denial he has shown in parting for their benefit with a valuable collection formed by the efforts of at least two preceding generations of his family.

L. FLETCHER.

PROPOSED NEW TELESCOPE FOR CAMBRIDGE OBSERVATORY.

IN order to complete the equipment of the Cambridge Observatory a public appeal has been made for funds. The appeal reads as follows:—

"It will be allowed that the Cambridge Observatory ought to be completely equipped for carrying on the most advanced work in modern astronomy. As celestial photography is the branch of astronomy in which the most important advance is now being made, it has been decided that a photographic telescope shall be obtained if the necessary funds be forthcoming. It is the opinion of those most competent to form a judgment that a photographic refractor of about 18 inches diameter would render it possible to attain results of the highest excellence. The new objective would be corrected for the photographic rays, and the present Northumberland telescope would serve as the guide when attached to the new tube. With such an exceptionally efficient instrument the director of the observatory would devote the attention of the staff (presently to be liberated by the termination of the international zone work on which it has been engaged for many years) to the investigation of stellar parallax. At the same time the telescope would be admirably adapted for other work. The twin instrument would be erected in the building at present occupied by the Northumberland equatorial, but a new dome, mounting, and driving clock would be required.

"The scheme sketched above has received the general sanction of the senate of the university, and the observatory syndicate are authorised to take the preliminary steps necessary to carry it out.

"The estimated cost for the new objective with the mounting, driving gear, and other adjuncts, is £2450. To this must be added £500 for the new dome, while the apparatus for measuring the photographs would cost £150. With the moderate allowance of £100 for extras, the total sum wanted is found to be £3200. The observatory syndicate have had under their consideration the means of providing this sum. There is a 'Special Sheepshanks Fund' available for the purchase of astronomical instruments for the Cambridge Observatory. This fund amounts at present to about £1500, of which about £1000 might be prudently expended. Accordingly about one-third of the money now required could be taken from the special Sheepshanks fund, whilst the remaining two-thirds would have to be raised otherwise. As the state of the university finances renders it hopeless to expect that any large sum could be forthcoming for this purpose from the university chest, it only remains to make an appeal to the public. The syndicate would therefore urge the friends of the University of Cambridge, and those interested in astronomical science, to render substantial aid in the furtherance of this project. They accordingly ask for donations towards the sum of £2200 which they have shown to be requisite for the full efficiency of the Cambridge Observatory.

Subscriptions will be received by Sir Robert Ball or by any of the following members of the observatory syndicate:—John Peile (vice-chancellor), G. G. Stokes, G. D. Liveing, G. H. Darwin, H. M. Taylor, and W. W. Rouse Ball. A list of subscriptions will be duly announced after replies to the appeal have been received.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE University Extension movement has hitherto received no assistance in the form of grants from the Government. But now that the movement is recognised as an educational power in the land it should be subsidised to a certain extent. As Prof. Stewart remarked in the course of a speech on the subject, delivered in connection with the summer meeting at Cambridge, "There was no sum of money that could be better spent by the State for educational purposes than a grant, say of £5,000 a year, to the university extension movement, because thereby they would render the £6,000,000 a year paid for elementary education so much more effective and productive, seeing that a very large proportion of university extension students were elementary school teachers." It was afterwards resolved: "That, in the opinion of this conference of university extension students, application should be made as early as possible to the Education Department for aid to university extension work, particularly for subjects not dealt with by the Technical Instruction Act."

UPRIGHT PENMANSHIP is rapidly becoming popular with the teachers and pupils in our schools, if we are to judge from the yearly growth in the number who send in copybooks to Mr. J. Jackson's annual competitions. The prize-list for 1893 just received contains four photographed specimens of prize-writing, and informs us that 1441 copybooks were sent in (as against 1121 in 1892). An eighth competition is announced for June 1894, when prizes to the amount of £60 will be awarded.

THE following is a complete list of the candidates to whom the University of London has awarded the degree of Doctor of Science this year:—Experimental Physics: Robert Wallace Stewart; Chemistry: Fredk. Daniel Chattaway and John Theodore Hewitt; Zoology: Henry Bargman Pollard; Animal Physiology: John William Pickering; Geology and Physical Geography: John Walter Gregory, William Fraser Hume, Maria Matilda Ogilvie.

SCIENTIFIC SERIALS.

Bulletin of the New York Mathematical Society, Vol. ii. No. 10. July 1893 (New York: Macmillan).—This young mathematical society crowns the previous good work of its *Bulletin*, in this, the concluding number of its second volume, by the translation and publication of Dr. Felix Klein's "programme on entering the philosophical faculty, and the senate of the University of Erlangen in 1872." It is entitled "A comparative review of recent researches in geometry" (pp. 215–249). The author prefixes a note in which he states that the programme had a limited circulation at first, with which he was then fairly well satisfied, but now that Lie's "Theorie der Transformationsgruppen" has appeared, and that an Italian translation has been published in the *Annali di Matematica*, it seems proper that a wider circulation should be given to his expositions. The translation, which is a literal one, has been admirably done by Dr. M. W. Haskell, and we feel sure that its publication will greatly extend Dr. Klein's *clientèle*. A few additional footnotes are supplied here and there. Dr. F. N. Cole continues his previous work with an article on "the transitive substitution-groups of nine letters" (pp. 250–258). He points out that Mr. Askwith (*Quar. Jour. of Mathematics*, vol. xxvi.) gives only 22 of the 34 actually existing types, and discusses the complete list of the transitive groups of this degree, with brief explanations of the processes by which he has obtained them. Prof. Ziwet gives a brief analysis (pp. 258, 9) of the "Index du répertoire bibliographique du Sciences Mathématiques, publié par la Commission permanente du répertoire" (Paris, 1893). Notes, lists of new publications, and the index complete the number.

IN the *Botanical Gazette* for July, Mr. D. M. Mottier has a paper on the embryo-sac and embryo of *Senecio aureus*; his results agree closely with those of Strasburger on *S. vulgaris*; Mr. P. Dietel describes a number of new specimens of Uredineæ and Ustilagineæ; Mr. G. F. Atkinson completes his account of the biology of the organism which causes tubercles in the roots of Leguminosæ; and Mr. C. Robertson contributes another to his series of articles on flowers and insects.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 15.—"On the Annual and Semi-annual Seismic Periods." By Charles Davison, M.A., Mathematical Master at King Edward's High School, Birmingham. Communicated by Prof. J. H. Poynting, F.R.S.

Method of Investigation.—The method adopted is similar to that employed by Dr. C. G. Knott in his paper on "Earthquake Frequency."

If $f(\theta)$ be a periodic function of θ, then

$$f(\theta) = a_0 + a_1 \cos(\theta + \alpha_1) + a_2 \cos(2\theta + \alpha_2) + \ldots a_n \cos(n\theta + \alpha_n) + \ldots,$$

from which it follows that

$$\frac{1}{\pi}\int_{\theta-\pi/2}^{\theta+\pi/2} f(\theta)d\theta = a_0 + \frac{2a_1}{\pi}\cos(\theta+\alpha_1) - \frac{2a_3}{3\pi}\cos(3\theta+\alpha_3) + \ldots + \frac{2a_n \sin\frac{n\pi}{2}}{n\pi}\cos(n\theta+\alpha_n) + \ldots.$$

This latter expression gives the mean value of $f(\theta)$ through an interval $\pi/2$ on either side of θ. From it, all terms involving even multiples of θ are eliminated, and the coefficients of all terms after the second are diminished to a greater extent than that of the second.

A definition of the unit earthquake having been adopted, the earthquakes of different districts are classified in half-monthly groups, the first half of February containing fourteen days, and of all the other months fifteen days; and the numbers so obtained are reduced to intervals of equal length (fifteen days). The numbers for the two halves of each month are added together. The mean of the numbers for the six months from November to April gives the six-monthly mean corresponding to the end of January. Six-monthly means are calculated in this way for the end of each month; each mean is divided by the average of all twelve, and the difference between each quotient and unity is multiplied by the augmenting factor 1·589, in order to obtain the correct value of the ratio $a_1 : a_0$. The curve obtained by plotting these reduced means thus gives special prominence to the annual period, by eliminating the semi-annual period and all those which are fractions of six months, and by diminishing the amplitudes of all other periods with respect to that of the annual period.

In investigating the semi-annual period, the numbers corresponding to the first halves of January and July are added together, and so on; the rest of the method being the same as for the annual period. The result gives special prominence to the semi-annual period by eliminating the annual period, and by eliminating or diminishing the amplitudes of all periods less than six months.

Seismic Periodicity in relation to Intensity.—This discussion is founded on: (1) lists compiled from Mallet's great catalogue, first, of shocks which were so slight as to be just perceptible, and, secondly, of those which were strong enough to damage buildings; (2) Prof. Milne's classification of the Japanese earthquakes of 1885 to 1889 according to the areas disturbed by them; and (3) different catalogues relating to the same district, it being obvious that two such catalogues for the same time can only differ by the omission or inclusion of slight shocks.

The following results are obtained:—(1) In both periods, the amplitude is greater for slight than for strong shocks; (2) there appear to be two classes of slight shocks with an annual period, the stronger having their maximum in winter, the weaker in summer; and (3) in the case of the semi-annual period, both strong and slight shocks, as a rule, have nearly the same maximum epochs.

Seismic Periodicity in relation to Geographical Position.—The number of records examined is 62, 45 belonging to the northern hemisphere, 14 to the southern, and 3 to equatorial countries.

1. *Annual Period.*—In every district, and in all but five records (which are obviously incomplete), there is a fairly well-marked annual period. As a rule, different records for the same district agree in giving the same, or nearly the same, maximun epoch. Excluding, however, those which disagree in this respect, we have left 34 records for the northern hemisphere, 9 for the southern, and 2 for equatorial countries. In the northern hemisphere, 4 records give the maximum in November, 16 in December, and 6 in January; in the southern hemisphere, 2 in April, 2 in May, 3 in July, and 2 in August; the end of the month being supposed in each case. As a rule, then, the maximum epoch occurs in winter in both hemispheres. The amplitude of the annual period ranges from 0·05 (New Zealand) to 0·67 (Sicily and Algeria), the average of 57 records being 0·33.

2. *Semi-Annual Period.*—Of the 62 records examined, only 3 fail to show a semi-annual period, the cause of the failure in these cases being no doubt the imperfection of the seismic record. In New Zealand and South-east Australia, the maximum epoch generally falls either in February or March and August or September; in North America, as a rule, in March or April and September or October. But for other regions it does not seem possible as yet to deduce any law. The amplitudes of the semi-annual period ranges from 0·06 (southern hemisphere) to 0·79 (Mexico), the average value being 0·24.

3. In fifteen cases, the amplitude of the semi-annual period exceeds that of the annual period. Eleven of these records include the following insular districts, which are among the most well-marked seismic regions in the world, namely, the Grecian Archipelago, Japan, the Malay Archipelago, New Zealand, and the West Indies. The average amplitude of the annual period in these eleven cases is 0·16, and that of the semi-annual period 0·24; *i.e.* the average amplitude of the annual period is just half that for all the districts examined, while in the case of the semi-annual period the average amplitudes are the same.

Origin of the Annual Period.—In this, the concluding, section of the paper, an attempt is made to show that the annual change in barometric pressure may be the cause of the annual change in seismic frequency. It would be difficult to prove that such a connection exists, but reasons are given which seem to render it in some degree probable.

1. The most probable cause of the origin of the majority of non-volcanic earthquakes is the impulsive friction, due to slipping, of the two rock-surfaces of a fault. Now, whatever be the causes of seismic periodicity, it seems probable that they are merely auxiliary, and determine the epoch when an earthquake shall take place, rather than there shall be an earthquake at all. Prof. G. H. Darwin has shown that the vertical displacement of the earth's surface by parallel waves of barometric elevation and depression is not inconsiderable, and that it diminishes at first very slowly as the depth increases. Since the fault-slip which produces even a moderately strong shock must be very small, and since the work to be done in such a case is, not the compression of solid rock, but the slight depression of a fractured mass whose support is nearly, but not quite, withdrawn, the annual range of barometric pressure does not seem incompetent to produce the effects observed.

2. Comparisons between the dates of the maximum epochs of the seismic and barometric annual periods are made in 31 of the districts treated in this paper. The seismic maximum approximately coincides with the barometric maximum in 10 districts, and follows it by about one month in 9, and by about two months in 4, districts; the other cases generally admitting of some explanation.

3. In several insular seismic districts, and especially in Japan and New Zealand, the amplitude of the annual period is very small; and, if many of the earthquakes of these districts originate beneath the sea, this should be the case; for, in the course of a year, as the barometric pressure changes, the sea will have time to take up its equilibrium position, and thus the total pressure on the sea-bottom will be unaltered.

PARIS.

Academy of Sciences, July 31.—M. de Lacaze-Duthiers in the chair.—Note on the work of M. D. Colladon, by M. Sarrau. M. J. D. Colladon, who died at Geneva on June 30, at the age of 91, was the first to transmit power to a distance by compressed air, and to utilise this power in boring tunnels. His system, proposed in 1852, was adopted in the working of the Cenis and Gothard tunnels. His name is also widely known in connection with improvements in paddle-wheels, and his celebrated investigation of the velocity of sound in the Lake of Geneva, in connection with Sturm.—Petroleum beds near Pechelbronn (Lower Alsace); exceptionally high temperatures observed there, by M. Daubrée. About twelve years ago the flooding of one of the petroleum mines of Pechelbronn by a sudden outbreak of the mineral oil suggested a substitution of boring and pumping for the laborious subterranean process, with the result that the yield was increased more than seventy times. The tertiary beds, which have an inclination of 7 or 8 per 100, are rich in gas, and the force with which the jets are projected when struck is sufficient to drench the men and produce a disturbance resembling an earthquake. It is calculated that all the sources together produce at present 80,000 kgr. of petroleum per day, and it is probable that many jets, if bored wide enough, would be capable of yielding 50,000 kgr. per day each. Some of the sources show a remarkable rise of temperature with increasing depth, reaching 1° for 7m. in one boring. This rise, contrary to the usual experience, becomes more rapid as the depth increases. M. Daubrée attributes both the occurrence of the oil and the extraordinary distribution of temperature to a particularly energetic internal activity, chemical or otherwise, of the globe at that point.—On the unequal resistance to drought exhibited by some largely cultivated plants, by M. P. P. Dehérain.—Observation of four simultaneous water-spouts at Antibes, by M. Naudin. These were observed on July 27, on the sea between Nice and Antibes. They were ranged very nearly in a straight line running east and west. The wind had suddenly veered from west to east and the water-spouts were produced at the junction of the two air-currents, and were observed to turn in a direction contrary to the hands of a watch. They lasted several minutes, gradually approaching the land, and broke on the hills near the shore.—Photography and physical observation of comet *b* 1893, made at the Juvisy Observatory, by M. F. Quénisset. A photograph was obtained by means of a Hermagis lens of 16 cm. aperture, the exposure being 40m., on July 19. The negative shows a double tail, one of them 1° long and pointing east, the other 30′ long and inclined towards the north.—An addition to the nomographic method recently described, allowing the introduction of another variable, by M. Maurice d'Ocagne.—On benzoylnicotine, by M. A. Étard.—On the fixation of iodine by starch, by M. G. Rouvier.—On the preparation of caproic and normal hexylic acids, by M. J. Tripier.—On gallate of mercury, a new antisyphilitic preparation, by MM. Brousse and Gay.—On virulent and epidemic cholera, by M. N. Gamaleia. The concentration of the nutrient medium, and the abundance of saline matter in the culture fluid gives rise to several slightly different variations of the cholera vibrio, which agree in being very much more virulent than the ordinary type. The author suspects an analogy between this fact and the observed dependance of the epidemic upon the conditions of desiccation of the soil and the level of subterranean waters.—On submarine photography, by M. Louis Boutan.—On the habits of *Blennius sphinx* and *Blennius montagui*, Fleming, by M. Frédéric Guitel.—On the cerebral nuclei of the myriapods, by M. Joannes Chatin.—Researches on the anatomy and development of the male genital apparatus of the orthopterous insects, by M. A. Peytoureau.—Anatomical characters of the stems of the Dioscoreæ, by M. C. Queva.—Development of the ground-nut, by M. A. Andouard.—On a trial of a screw for vertical propulsion, by M. Mallet. A Langlois air propeller of 2·5 m. diameter was attached to the car of a balloon of 800 m³. capacity, and worked by the muscular power of the aeronauts. During one minute the balloon was raised 100 m., sinking again to its former level on stopping the propeller.

THURSDAY, AUGUST 17, 1893.

OLD AND NEW ASTRONOMY.

Old and New Astronomy. By Richard A. Proctor, completed by A. Cowper Ranyard. (London: Longmans, Green and Co., 1892.)

As originally designed by Mr. Proctor, this work was to contain a complete account of the Old and New Astronomy, particular attention being paid to the latter portion, which he wished to make a special feature of the book. It was to be issued in twelve monthly parts, the first of which duly appeared in March 1888; but unfortunately Mr. Proctor did not live to complete what he intended to be his *magnum opus*, and at the time of his death in September 1888 only seven parts were in type and the manuscript of the chapters on the planets well advanced. Although a considerable proportion of the materials for the chapters on the new astronomy had been collected, nothing had been written for that portion of the book. Mr. Ranyard undertook to complete the work, and as we now have it five-sixths of the book deals with the ancient and old astronomy, and is due to Mr. Proctor; while the remaining portion by Mr. Ranyard deals with some of the work and problems of the new astronomy. Unfortunately the book had grown to such an enormous size that promised chapters on meteors and comets were omitted and we have the strange anomaly of a work on astronomy in which neither of these important phenomena are dealt with.

It is to be regretted that Mr. Ranyard, in finishing the book, did not attempt to draw up a list of the errata which "must inevitably occur in a work of this kind," and that he did not see fit to add in some places details of important points, the original omission of which was probably accidental. For instance, in the first chapter, which gives an account of ancient and modern methods of observing the heavenly bodies, we find it indicated that the reflecting telescope suffers from chromatic aberration (page 45); and although stress is laid on the "amazingly exact system of modern measurement" the two essential instruments, the filar micrometer and the chronograph, are not even mentioned. Later on, in dealing with spectroscopy, the diffraction grating is not dealt with, and there is no mention of the grating spectroscope. We venture to think that no work on astronomy can be considered complete in which such essentials to the proper comprehension of the subject are omitted.

In the chapters on the shape of the earth, the apparent motions of the sun, moon, and planets, the true mechanism of the solar system, and the measuring and weighing of the solar system, we find Mr. Proctor probably at his best, the subjects being treated in considerable detail, although there is very little that has not already appeared in his earlier works.

Two chapters are devoted to the sun and its surroundings, and here Mr. Proctor differs from most of the authorities on the subject. He assumes that the formation of a spot is usually preceded by the formation of a facula, although the subject is still under discussion and the weight of evidence at present is distinctly in favour of the opposite conclusion. Now that Prof. Hale has enabled us to supplement our photographic study of sun-spots by photographs of all the faculæ on the solar disc, we may shortly hope to be able to fully trace the life history of solar disturbances in particular regions of the sun, and so to obtain a firm basis for a definite conclusion in the matter. We are also told in this chapter that we are forced to the conclusion that sun-spots are produced in the main by uprushes of intensely heated vapours from below the photosphere, but the generally accepted view is that spots are due to downrushes of comparatively cool matter from the regions above the photosphere. The main objection to the view that sun-spots are due to uprushes of intensely heated matter is that the bright lines in sun-spot spectra are few, and are not those usually associated with extremely high temperature.

The interesting chapter on the sun's surroundings is marred by personalities which render it practically impossible to consider this portion of the book as dispassionate scientific work. We may mention, however one error of fact which Mr. Ranyard should have corrected. On page 408 we are told that the eclipse of 1860 is remarkable as the first in which photography was employed to secure views of the corona, whereas Majocchi, at Milan, in 1842, had unsuccessfully tried this method of observation; and Berkowski, July 28, 1851, had obtained a perfectly successful picture showing the prominences and corona.

The chapters on the planets are, as might have been expected, very full and complete, but contain little that is new or calls for special comment. The method of illustrating the seasons on the earth by a series of diagrams, showing our planet as seen from the sun at 6 a.m., midday, 6 p.m., and midnight at Greenwich, on one day in each month, may, however, be noticed as certainly an advance on the very unsatisfactory method usually found in works on astronomy. It is also interesting to note that the moon is properly considered as a planet.

In the discussion of the temperature of the lunar surface, we are told that merely theoretical considerations could be thoroughly relied upon as proving that the temperature during the lunar day exceeds that of boiling water; and Lord Rosse's measurements which indicate a temperature of fully 500° Fahrenheit, are accepted, while those of Prof. Langley, which assign a temperature below freezing point, are rejected as being affected by some unknown cause of error. Later researches by Mr. Boys have, however, confirmed Prof. Langley's results, and it would have been an advantage had Mr. Ranyard noted this in the completed volume.

In the chapters on stars and the new astronomy Mr. Ranyard gives in the beginning a full account of parallax, and presents an interesting diagram showing the distances of all stars whose parallaxes have been determined during the present century. The theories of the earlier astronomers with regard to the construction of the stellar universe are passed in rapid review, due credit being awarded to the work of Thomas Wright, of Durham, who really anticipated many of the speculations of Sir William Herschel. The various later disc, ring, and spiral theories of the Milky Way are carefully discussed and compared with the latest researches of Prof. E. C. Pickering and Dr. Gould, the whole object of the work being obviously to give a full and fair statement of fact, without regard to any preconceived ideas or theories. The distribution of nebulæ is then considered, and a careful analysis made of the many wonderful structures shown in Dr. Robert's photograph of the great nebula in Orion. The great similarity of these forms to those traceable in the Solar Corona is clearly demonstrated, and it is suggested that just as the coronal forms probably have their origin in enormous streams of gaseous matter ejected into a resisting medium, so these similar structures may be due to a similar cause. Mr. Ranyard then shows how these forms are reproduced in the arrangement of clouds of stars in the Milky Way, as shown by the marvellous photographs taken by Prof. E. E. Barnard of the Lick Observatory, excellent reproductions of which illustrate this portion of the book. A detailed examination of Prof. Barnard's plates seems to Mr. Ranyard to indicate the existence of dark-absorbing matter, "either like cold gas or fog of opaque particles in space, cutting out or dimming down the light of the region beyond." These dark patches assume the curved forms and tree-like structure already referred to, and thus seem to further confirm the idea of a resisting medium, which, as Mr. Ranyard is careful to point out, need not necessarily be a gas; dust moving in space, or meteors, or large masses would equally offer resistance.

By deliberately overprinting photographs of the Milky Way, long chains of stars and curving dark lanes have been brought into great prominence, and have materially assisted in the investigation. There is certainly much to recommend this startling suggestion of dark absorbing matter in space, and the wonderful details of Prof. Barnard's photographs, and the similarity to coronal and nebular forms, can scarcely be explained as due to accidental groupings of stars and dark spaces in the Milky Way. Although most authorities, including Prof. Barnard himself, prefer to suspend their judgment in the matter until still more photographic results are available, there can be little doubt that no more satisfactory hypothesis has as yet been advanced.

The connection between nebulæ and bright stars, and the connection of bright stars with faint ones by means of thin wisps of nebulous matter, undoubtedly indicate that differences in magnitude of stars are due to differences of physical condition and not to distance. As illustrating the far-reaching results of this conclusion Mr. Ranyard says:—

"If we assume a distance fifteen times as great as the distance of α Centauri, for a part of the Milky Way in which a first magnitude star is found to be associated with stars of the $17\frac{1}{2}$ magnitude, we must be prepared to assume a diameter for the large star twenty times as great as the solar diameter, unless its photosphere is brighter than the solar photosphere; while the smaller stars if their photospheres were as brilliant as the solar photosphere, would have diameters equal to about one-hundredth part of the solar diameter—that is, they would not much exceed the earth in magnitude."

The question of proper motion next receives attention, and this is followed by an account of binary and triple stars, most of the recent work being fully dealt with. In the discussion of stellar spectroscopy we find Secchi's classification of star spectra given to the exclusion of all others. Details of other systems might well have been introduced here, but it is evident that Mr. Ranyard considers the subject one in which very little advance towards a proper classification has been made. He is of opinion (p. 795) that the Sirian type are less condensed and are in an earlier stage than the solar type, and indicates that bright line stars must come somewhere between nebulæ and the Sirian type; but there is nothing to indicate whether he thinks this is the stage of rising or falling temperature, and the whole question is left in a vague and somewhat unsatisfactory manner.

In considering the supposed physical connection between the stars in the great nebula in Orion and the nebula itself, Mr. Ranyard relies on the fact that similar bright lines are found in the spectra of each, and quotes the photographs of Dr. Huggins as proving that these stars are physically bound up with the gaseous matter of the nebula. He himself seems inclined to the opinion that they are not condensations of the nebulæ, but are the centres from which the matter now forming the nebula was ejected; but whether condensations of the nebula or points of origin the spectra are supposed to be similar. It is important to remember, however, that it is nearly impossible to get a photograph of the spectrum of a star involved in a nebula without also obtaining a superposed spectrum of the nebula itself. Every tremor of the telescope sufficient to carry the star image off the slit will allow the nebula to imprint its spectrum on the plate, and if the star is allowed to trail along the slit it is clear that the nebula gets more exposure than the star at any particular point in the resulting photograph. There is at present no absolute photographic proof that the stars in the nebula in Orion contain the nebular lines as bright lines in their spectra, and consequently conclusions based on this assumption are untrustworthy.

Mr. Ranyard classes the nebulæ which give faint continuous spectra and do not show the characteristic green line, as white nebulæ, and places in this class the Andromeda nebula, the spiral in Canes Venatici, and the nebulous background of the Milky Way, but makes no suggestion as to the stage of development of these bodies.

On the question of "What is a nebula?" it is extremely difficult to understand the exact position assumed by Mr. Ranyard. He evidently considers nebulæ as containing solid or liquid matter and as increasing in temperature, but "the very great transparency" renders it probable that they either contain very little solid or liquid matter, or that the solid or liquid matter is aggregated into discrete masses with an average diameter of more than an inch; if the density of a nebula, leaving out of account its gaseous constituents, is as much as one one-thousand millionth of the density of atmospheric air at the sea level. These conclusions are practically an acceptance of the main idea of Lockyer's meteoritic hypothesis so far as it deals with nebulæ, although Mr. Ranyard rejects the spectroscopic evidence bearing on the point. The speculations as to the probable density of the Great Orion nebula, although extremely interesting, are vitiated by the fact that it is impossible to estimate the gravitational effect of the dark matter in interstellar space.

The book is well and copiously illustrated throughout, the plates and the photographic reproductions being of a very high-class character. Mr. Proctor's portion is written in his usual clear and popular manner, but the prevailing impression is decidedly that of disproportion. Too much space is occupied by the personalities which were unfortunately too frequently shown in his controversial methods, and by details of a comparatively unimportant character; while essentials are, as we have pointed out, frequently incompletely dealt with or even entirely omitted.

Mr. Ranyard's portion is admirably written, is very thoughtful and suggestive, and is a valuable contribution to our knowledge of the stellar universe and the condition and distribution of matter in external space. Indeed, the comparative brevity of this portion of the book is its chief fault, and a condensation of the earlier portion to allow of the expansion of this would greatly increase its value to the student, and would certainly not lessen its interest to the general reader. A. T.

EARTHQUAKES.

Erdbebenkunde. Die Erscheinungen und Ursachen der Erdbeben, die Methoden ihrer Beobachtungen. Von Dr. Rudolf Hoernes, o.ö. Professor der Geologie und Palæontologie an der Universität Graz. (Leipzig: Veit and Co., 1893.)

Étude sur les Tremblements de Terre. Par Léon Vinot. (Paris and Nancy: Berger-Levrault et Cie, 1893.)

IN a recent article in this journal, entitled "Seismology in Japan" (see NATURE, June 8, p. 136) attention was directed to the long series of memoirs which deal with the methods and results of earthquake-observation, and have appeared in the Transactions of the Seismological Society of Japan, or its successor, the *Seismological Journal of Japan.* Any advance in our knowledge of the phenomena or causes of earthquakes resulting from the study of the frequently occurring shocks in Japan is largely due to the untiring efforts of the editor of those journals, Prof. John Milne, and to those of the school of active seismologists, whom he has educated and inspired with some of his own enthusiasm. We can best judge, perhaps, how far advances of our knowledge on this difficult and obscure department of physics and geology have been real and of permanent value from the examination of text-books and general treatises, in which summaries are given of the latest and most important researches upon the subject.

The two works whose titles appear at the head of this article, and which have recently made their appearance in Germany and France respectively, may well serve the purpose of illustrating what is the high-water mark of our knowledge at the present time concerning these remarkable but little understood phenomena.

If we compare these two books with their numerous predecessors, the first peculiarity which strikes us is the classification of earthquake-phenomena, based on the supposed causes of the disturbance of equilibrium in the earth's solid crust, which have been adopted by the recent authors. While the older writers took for granted the close connexion between seismological and vulcanological phenomena, so that "earthquakes and volcanoes" were almost always discussed in the same treatise, the two works before us afford distinct evidence that this conviction has now been very seriously shaken. It is true that nearly all great volcanic outbursts have been attended by earth-tremblings; but it is equally true that some of the grandest displays of seismic energy have occurred in areas that have not at any recent period been the scenes of volcanic activity; and both the German and the French author admit the existence of great classes of seismic disturbances, which have no necessary connexion with any manifestations of volcanic energy.

Dr. Hoernes classifies earthquakes under the four headings: "Vulkanische Beben," "Einsturzbeben," "Dislocationsbeben," and "Relaisbeben." M. Vinot treats of them under the following heads:—"Tremblements de terre suivis, d'éruptions où liés directement à l'action volcanique;" "Tremblements de terre dus encore à l'action direct du feu central, mais sans manifestation consécutive du volcanisme;" and, lastly, "Tremblements de terre indépendent de l'action volcanique."

But with this recognition of the class of non-volcanic earthquakes the resemblance between these two books ceases. Dr. Hoernes commences his work with an admirable account of the speculations on the nature and causes of earthquake-phenomena which have appeared from the earliest times. His comprehensive sketch begins with extracts from the writings of Hebrew prophets and Greek philosophers, and ends with references to the Seismological Society of Japan. The two chapters which follow on earthquake-phenomena and earthquake-observation are clear and useful summaries of the most recent researches on the subject, and are well brought up to date. Supplied as they are with drawings and descriptions of seismographic apparatus, they afford one of the best guides with which we are acquainted to a general knowledge of the principles and methods of seismological investigation.

M. Vinot commences his work with a chapter on the nebular hypothesis and the proofs of the existence of central heat within the earth. He insists that, to explain the phenomena of earthquakes, it is necessary to assume the existence at a depth which certainly does not exceed "quelques centaines des kilomètres," of a mass of incandescent liquid materials, which he argues must consist of molten metals in which are dissolved certain gases. The subsequent chapters of his book are a series of deductions from these premises. It will thus be seen that the methods and plan of the German and French authors are about as diverse as can well be conceived. The German work abounds with references by means of which the student who is not satisfied with the summary statements in the text is enabled to put himself into communication with the memoirs of the original investigator whose views have been cited. The French work is simply a readable essay, in which we have none of these valuable aids to study. The illustrations of M. Vinot's book consist of several page plates, reproduced from photographs, and representing the now-destroyed terraces of Rotomahana in New Zealand and the country affected by the eruption of Tarawera but the connexion of these illustrations with the text is by no means obvious.

In two works so diverse in their plan and execution as are those before us, it is interesting to note yet another and somewhat unexpected feature which they present in common. That M. Vinot should commence his book with references to the Deluge, the destruction of Sodom and Gomorrah, and the giving of the law on Sinai, seems perfectly natural. But most readers will note with some surprise that the last chapter of Dr. Hoernes's book is one entitled "Die Sintfluth." We cannot but regard it as a remarkable testimony to the profound influence of that striking and suggestive book of Dr. Suess, "Das Antlitz der Erde," that this chapter should have been added by Dr. Hoernes to his systematic treatise on Earthquakes. It is scarcely necessary to point out that the flood to which the Austrian geologist devotes the final chapter of his treatise is the deluge, not of Sir Henry Howorth, but of Noah and Hasîs-Adra, and that the connexion between this final chapter and the preceding ones is of the very slenderest character. But the legends of our own childhood and of the childhood of our race have a fascination for us, which neither the brilliant French essayist nor the painstaking German professor seem to have been able to resist.

OUR BOOK SHELF.

The Points of the Horse. By M. Horace Hayes, F.R.C.V.S. (London: W. Thacker and Co., 1893.)

IT is certainly curious that although the English nation justly prides itself on its knowledge of horse flesh, and its success in producing the various equine breeds, it should possess no work dealing in an exact and scientific manner with the conformation of the animal that it has done so much to improve. That certain shapes are indicative of great speed, whilst others point to strength rather than speed, has, of course, always been insisted upon in a general way, but it has been left to Captain Hayes to imitate the example of several French authors, and deal with the subject in a scientific spirit. A soldier, a certificated veterinarian, a traveller, and a successful rider, the author is well qualified to treat of all that pertains to the subject before us. The work represents a painstaking endeavour to discover and explain the various principles which govern the make and shape of the horse.

Starting with a study of animals like the Indian black buck and cheetah, which possess terrific speed, he compares them with others such as the buffalo and rhinoceros, which are examples of great strength, a comparison which leads to the conclusion that animals of great strength are distinguished by a long body and short legs; those of great speed by a short body and long legs. This is an exemplification of Marey's law that muscles of speed are long and slender, and those of strength short and thick. Whether it was necessary to stray so far from home to find examples of this fact may be doubted. The thoroughbred racehorse on the one hand, and the massive carthorse on the other, are surely sufficiently contrasted types of speed and strength, whilst between the two extremes are numerous examples exhibiting the union of these two attributes in various degrees, the hunter, for example, uniting considerable strength with moderate speed.

The defects as well as many of the beauties of conformation are admirably depicted in a series of photographs, such defects as turned-in and turned-out toes, sickle-shaped hocks, and upright pasterns, being particularly good. The photographic plates, of which there are over seventy, certainly constitute an important feature in the work, embracing, in addition to the above, portraits of many celebrated racers, notably "Ormonde" and "St. Simon," as well as horses and ponies of various breeds found in different parts of the globe. A chapter is devoted to an examination of these photographs, the leading features and points of the animals represented being analysed and commented upon. It would be unfair in this connection to omit favourable mention of the 200 excellent drawings by the late J. H. Oswald Brown, which serve throughout the work to illustrate the letterpress.

Author, artist, and publisher have successfully united in producing a first-rate work, which may be cordially recommended to all lovers—and their name is legion—of the horse. W. F. G.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Quaternions and Vector Analysis.

IN a paper by Prof. C. G. Knott on "Recent Innovations in Vector Theory," of which an abstract has been given in NATURE (vol. xlvii. pp. 590–593; see also a minor abstract on p. 287), the doctrine that the quaternion affords the only sufficient and proper basis for vector analysis is maintained by arguments based so largely on the faults and deficiencies which the author has found in my pamphlet, "Elements of Vector Analysis," as to give to such faults an importance which they would not otherwise possess, and to make some reply from me necessary, if I would not discredit the cause of non-quaternionic vector analysis. Especially is this true in view of the warm commendation and endorsement of the paper, by Prof. Tait, which appeared in NATURE somewhat earlier (p. 225)

The charge which most requires a reply is expressed most distinctly in the minor abstract, viz. "that in the development of his dyadic notation, Prof. Gibbs, being forced to bring the quaternion in, logically condemned his own position." This was incomprehensible to me until I received the original paper, where I found the charge specified as follows: "Although Gibbs gets over a good deal of ground without the explicit recognition of the complete product, which is the difference of his 'skew' and 'direct' products, yet even he recognises in plain language the versorial character of a vector, brings in the quaternion whose vector is the difference of a linear vector function and its conjugate, and does not hesitate to use the accursed thing itself in certain line, surface, and volume integrals" (Proc. R.S.E., Session 1892-3, p. 236). These three specifications I shall consider in their inverse order, premising, however, that the *epitheta ornantia* are entirely my critic's.

The last charge is due entirely to an inadvertence. The integrals referred to are those given at the close of the major abstract in NATURE (p. 593). My critic, in his original paper, states quite correctly that, according to my definitions and notations, they should represent dyadics. He multiplies them into a vector, introducing the vector under the integral sign, as is perfectly proper, provided, of course, that the vector is constant. But failing to observe this restriction, evidently through inadvertence, and finding that the resulting equations (thus interpreted) would not be true, he concludes that I must have meant something else by the original equations. Now, these equations will hold if interpreted in the quaternionic sense, as is, indeed, a necessary consequence of their holding in the dyadic sense, although the converse would not be true. My critic was thus led, in consequence of the inadvertence mentioned, to suppose that I had departed from my ordinary usage and my express definitions, and had intended the products in these integrals to be taken in the quaternionic sense. This is the sole ground for the last charge.

The second charge evidently relates to the notations Φ_s and $\Phi_\times$ (see NATURE, vol. xlvii. p. 592). It is perfectly true that I have used a scalar and a vector connected with the linear vector operator, which, if combined, would form a quaternion. I have not thus combined them. Perhaps Prof. Knott will say that since I use both of them it matters little whether I combine them or not. If so I heartily agree with him.

The first charge is a little vague. I certainly admit that vectors may be used in connection with and to represent rotations. I have no objection to calling them in such cases *versorial*. In that sense Lagrange and Poinsot, for example, used versorial vectors. But what has this to do with quaternions? Certainly Lagrange and Poinsot were not quaternionists.

The passage in the major abstract in NATURE which most distinctly charges me with the use of the quaternion is that in which a certain expression which I use is said to represent the quaternion operator $q(\quad)q^{-1}$ (vol. xlvii. p. 592). It would be more accurate to say that my expression and the quaternionic expression represent the same operator. Does it follow that I have used a quaternion? Not at all. A quaternionic expression may represent a number. Does everyone who uses any expression for that number use quaternions? A quaternionic expression may represent a vector. Does everyone who uses any expression for that vector use quaternions? A quaternionic expression may represent a linear vector operator. If I use an expression for that linear vector operator do I therefore use quaternions? My critic is so anxious to prove that I use quaternions that he uses arguments which would prove that quaternions were in common use before Hamilton was born.

So much for the alleged use of the quaternion in my pamphlet. Let us now consider the faults and deficiencies which have been found therein and attributed to the want of the quaternion. The most serious criticism in this respect relates to certain integrating operators, which Prof. Tait unites with Prof. Knott in ridiculing. As definitions are wearisome, I will illustrate the use of the terms and notations which I have used by quoting a sentence addressed to the British Association a few years ago. The speaker was Lord Kelvin.

"Helmholtz first solved the problem—Given the spin in any case of liquid motion, to find the motion. His solution consists in finding the potentials of three ideal distributions of gravitational matter having densities respectively equal to $1/\pi$ of the rectangular components of the given spin; and, regarding for a moment these potentials as rectangular components of velocity in a case of liquid motion, taking the spin in this motion as the velocity in the required motion" (NATURE, vol. xxxviii. p. 569).

In the terms and notations of my pamphlet the problem and solution may be thus expressed:

Given the curl in any case of liquid motion—to find the motion.

The required velocity is $1/4\pi$ of the curl of the potential of the given curl.

Or, more briefly—The required velocity is $\frac{1}{4\pi}$ of the Laplacian of the given curl.

Or in purely analytical form—Required ω in terms of $\nabla \times \omega$, when $\nabla . \omega = 0$.

Solution—

$$\omega = 1/4\pi \nabla \times \text{Pot}\, \nabla \times \omega = 1/4\pi\, \text{Lap}\, \nabla \times \omega.$$

(The Laplacian expresses the result of an operation like that by which magnetic force is calculated from electric currents distributed in space. This corresponds to the second form in which Helmholtz expressed his result.)

To show the incredible rashness of my critics, I will remark that these equations are among those of which it is said in the original paper (Proc. R.S.E., Session 1892–93, p. 225), "Gibbs gives a good many equations—theorems I suppose they ape at being." I may add that others of the equations thus characterised are associated with names not less distinguished than that of Helmholtz. But that to which I wish especially to call attention is that the terms and notations in question express exactly the notions which physicists want to use.

But we are told (NATURE, vol. xlvii. p. 287) that these integrating operators (Pot, Lap) are best expressed as inverse functions of ∇. To see how utterly inadequate the Nabla would have been to express the idea, we have only to imagine the exclamation points which the members of the British Association would have looked at each other if the distinguished speaker had said:

Helmholtz first solved the problem—Given the Nabla of the velocity in any case of liquid motion, to find the velocity. His solution was that the velocity was the Nabla of the inverse square of Nabla of the Nabla of the velocity. Or, that the velocity was the inverse Nabla of the Nabla of the velocity.

Or, if the problem and solution had been written thus: Required ω in terms of $\nabla\omega$ when $S\nabla\omega = 0$.

Solution: $\omega = \nabla\nabla^{-2}\nabla\omega = \nabla^{-1}\nabla\omega.$

My critic has himself given more than one example of unfitness of the inverse Nabla for the exact expression of thought. For example, when he says that I have taken "eight distinct steps to prove two equations, which are special cases of

$$\nabla^{-2}\nabla^2 u = u,"$$

I do not quite know what he means. If he means that I have taken eight steps to prove Poisson's Equation (which certainly is not expressed by the equation cited, although it may perhaps be associated with it in some minds), I will only say that my proof is not very long, especially as I have aimed at greater rigour than is usually thought necessary. I cannot, however, compare my demonstration with that of quaternionic writers, as I have not been able (doubtless on account of insufficient search) to find any such.

To show how little foundation there is for the charge that the deficiencies of my system require to be pieced out by these integral operators, I need only say that if I wished to economise operators I might give up New, Lap, and Max, writing for them ∇ Pot, $\nabla \times$ Pot, and $\nabla .$ Pot, and if I wished further to economise in what costs so little, I could give up the potential also by using the notation $(\nabla . \nabla)^{-1}$ or ∇^{-2}. That is, I could have used this notation without greater sacrifice of precision than quaternionic writers seem to be willing to make. I much prefer, however, to avoid these inverse operators as essentially indefinite.

Nevertheless—although my critic has greatly obscured the subject by ridiculing operators, which I beg leave to maintain are not worthy of ridicule, and by thoughtlessly asserting that it was necessary for me to use them, whereas they are only necessary for me in the sense in which something of the kind is necessary for the quaternionist also, if he would use a notation irreproachable on the score of exactness—I desire to be perfectly candid. I do not wish to deny that the relations connected with these notations appear a little more simple in the quaternionic form. I had, indeed, this subject principally in mind when I said two years ago in NATURE (vol. xliii. p. 512): "There are a few formulæ in which there is a trifling gain in compactness in the use of the quaternion." Let us see exactly how much this advantage amounts to.

There is nothing which the most rigid quaternionist need object to in the notation for the potential, or indeed for the Newtonian. These represent respectively the operations by which the potential or the force of gravitation is calculated from the density of matter. A quaternionist would, however, apply the operator *New* not only to a scalar, as I have done, but to a vector also. The vector part of New ω (construed in the quaternionic sense) would be exactly what I have represented by Lap ω, and the scalar part, taken negatively, would be exactly what I have represented by Max ω. The quaternionist has here a slight economy in notations, which is of less importance, since all the operators—New, Lap, Max—may be expressed without ambiguity in terms of the potential, which is therefore the only one necessary for the exact expression of thought.

But what are the formulæ which it is necessary for one to remember who uses my notations? Evidently only those which contain the operator *Pot*. For all the others are derived from these by the simple substitutions

$$\text{New} = \nabla\, \text{Pot},$$
$$\text{Lap} = \nabla \times \text{Pot},$$
$$\text{Max} = \nabla .\, \text{Pot}.$$

Whether one is quaternionist or not, one must remember Poisson's Equation, which I write

$$\nabla . \nabla\, \text{Pot}\, \omega = -4\pi\omega,$$

and in quaternionic might be written

$$\nabla^2\, \text{Pot}\, \omega = 4\pi\omega.$$

If ω is a vector, in using my equations one has also to remember the general formulæ,

$$\nabla . \nabla\omega = \nabla\nabla . \omega - \nabla \times \nabla \times \omega$$

which as applied to the present case may be united with the preceding in the three-membered equation,

$$\nabla . \nabla\, \text{Pot}\, \omega = \nabla\nabla .\, \text{Pot}\, \omega - \nabla \times \nabla \times\, \text{Pot}\, \omega = -4\pi\omega.$$

This single equation is absolutely all that there is to burden the memory of the student, except that the symbols of differentiation (∇, $\nabla \times$, $\nabla .$) may be placed indifferently before or after the symbol for the potential, and that if we choose we may substitute as above *New* for ∇ Pot, &c. Of course this gives a good many equations, which on account of the importance of the subject (as they might almost be said to give the mathematics of the electro-magnetic field) I have written out more in detail than might seem necessary. I have also called the attention of the student to many things, which perhaps he might be left to himself to see. Prof. Knott says that the quaternionist obtains similar equations by the simplest transformations. He has failed to observe that the same is true in my *Vector Analysis*, when once I have proved Poisson's Equation. Perhaps he takes his model of brevity from Prof. Tait, who simplifies the subject, I believe, in his treatise on Quaternions, by taking this theorem for granted.

Nevertheless, since I am forced so often to disagree with Prof. Knott, I am glad to agree with him when I can. He says in his original paper (p. 226), "No finer argument in favour of the real quaternion vector analysis can be found than in the tangle and the jangle of sections 91 to 104 in the 'Elements of Vector Analysis.'" Now I am quite ready to plead guilty to the tangle. The sections mentioned, as is sufficiently evident to the reader, were written at two different times, sections 102–104 being an addition after a couple of years. The matter of these latter sections is not found in its natural place, and the result is well enough characterised as a *tangle*. It certainly does credit to the conscientious study which Prof. Knott has given to my pamphlet, that he has discovered that there is a violent dislocation of ideas just at this point. For such a fault of composition I have no sufficient excuse to offer, but I must protest against its being made the ground of any broad conclusions in regard to the fundamental importance of the quaternion.

Prof. Knott next proceeds to criticise—or, at least, to ridicule—my treatment of the linear vector function, with respect to which we read in the abstract:—"As developed in the pamphlet, the theory of the dyadic goes over much the same ground as is traversed in the last chapter of Kelland and Tait's 'Introduction to Quaternions.' With the exception of a few of those lexicon products, for which Prof. Gibbs has such an affection, there is nothing of real value added to our knowledge of the linear vector function." It would not, I think, be difficult to show some inaccuracy in my critic's characterisation of the real content of this part of my pamphlet. But as algebra is a formal science, and as the whole discussion is concerning the best form of representing certain kinds of relations, the important question would seem to be whether there is anything of *formal* value in my treatment of the linear vector function.

Now, Prof. Knott distinctly characterises in half a dozen words the difference in the spirit and method of my treatment of this subject from that which is traditional among quaternionists, when he says of what I have called dyadics—"these are not quantities, but operators" (NATURE, vol. xlvii. p. 592) I do not think that I applied the word quantity to the dyadics, but Prof. Knott recognised that I treated them as quantities—not, of course, as the quantities of arithmetic, or of ordinary algebra, but as quantities in the broader sense, in which, for example, quaternions are called quantities. The fact that they may be operators does not prevent this. Just as in grammar verbs may be taken as substantives, viz. in the infinitive mood, so in algebra operators—especially such as are capable of quantitative variation—may be regarded as quantities when they are made the subject of algebraic comparison or operation. Now I would not say that it is necessary to treat every kind of operator as quantity, but I certainly think that one so important as the linear vector operator, and one which lends itself so well to such broader treatment, is worthy of it. Of course, when vectors are treated by the methods of ordinary algebra, linear vector operators will naturally be treated by the same methods, but in an algebra formed for the sake of expressing the relations between vectors, and in which vectors are treated as multiple quantities, it would seem an incongruity not to apply the methods of multiple algebra also to the linear vector operator.

The dyadic is practically the linear vector operator regarded as quantity. More exactly it is the multiple quantity of the ninth order which affords various operators according to the way in which it is applied. I will not venture to say what ought to be included in a treatise on quaternions, in which, of course, a good many subjects would have claims prior to the linear vector operator; but for the purposes of my pamphlet, in which the linear vector operator is one of the most important topics, I cannot but regard a treatment like that in Hamilton's "Lectures," or "Elements," as wholly inadequate *on the formal side*. To show what I mean, I have only to compare Hamilton's treatment of the quaternion and of the linear vector operator with respect to notations. Since quaternions have been identified with matrices, while the linear vector operator evidently belongs to that class of multiple quantities, it seems unreasonable to refuse to the one those notations which we grant to the other. Thus, if the quaternionist has e_q, $\log q$, $\sin q$, $\cos q$, why should not the vector analyst have $e\Phi$, $\log \Phi$, $\sin \Phi$, $\cos \Phi$, where Φ represents a linear vector operator? I suppose the latter are at least as useful to the physicist. I mention these notations first, because here the analogy is most evident. But there are other cases far more important, because more elementary, in which the analogy is not so near the surface, and therefore the difference in Hamilton's treatment of the two kinds of multiple quantity not so evident. We have, for example, the tensor of the quaternion, which has the important property represented by the equation—$T(qr) = TqTr$.

There is a scalar quantity related to the linear vector operator, which I have represented by the notation $|\Phi|$ and called the *determinant* of Φ. It is in fact the determinant of the matrix by which Φ may be represented, just as the square of the tensor of q (sometimes called the *norm* of q) is the determinant of the matrix by which q may be represented. It may also be defined as the product of the latent roots of Φ, just as the square of the tensor of q might be defined as the product of the latent roots of q. Again, it has the property represented by the equation

$$|\Phi \cdot \Psi| = |\Phi||\Psi|$$

which corresponds exactly with the preceding equation with both sides squared.

There is another scalar quantity connected with the quaternion and represented by the notation Sq. It has the important property expressed by the equation,

$$S(qrs) = S(rsq) = S(sqr),$$

and so for products of any number of quaternions, in which the cyclic order remains unchanged. In the theory of the linear vector operator there is an important quantity which I have represented by the notation Φ_s, and which has the property represented by the equation

$$(\Phi \cdot \Psi \cdot \Omega)_s = (\Psi \cdot \Omega \cdot \Phi)_s = (\Omega \cdot \Phi \cdot \Psi)_s$$

where the number of the factors is as before immaterial. Φ_s may be defined as the sum of the latent roots of Φ, just as $2Sq$ may be defined as the sum of the latent roots of q.

The analogy of these notations may be further illustrated by comparing the equations

$$T(e_q) = e^{Sq}$$

and

$$|\epsilon\Phi| = e\Phi_s.$$

I do not see why it is not as reasonable for the vector analyst to have notations like $|\Phi|$ and Φ_s as for the quaternionist to have the notations Tq and Sq.

This is of course an *argumentum ad quaternionisten*. I do not pretend that it gives the reason why I used these notations, for the identification of the quaternion with a matrix was, I think, unknown to me when I wrote my pamphlet. The real justification of the notations $|\Phi|$ and Φ_s is that they express functions of the linear vector operator *quâ* quantity, which physicists and others have continually occasion to use. And this justification applies to other notations which may not have their analogues in quaternions. Thus I have used $\Phi_\times$ to express a vector so important in the theory of the linear vector operator, that it can hardly be neglected in any treatment of the subject. It is described, for example, in treatises as different as Thomson and Tait's *Natural Philosophy* and Kelland and Tait's *Quaternions*. In the former treatise the components of the vector are, of course, given in terms of the elements of the linear vector operator, which is in accordance with the method of the treatise. In the latter treatise the vector is expressed by

$$V\alpha\alpha' + V\beta\beta' + V\gamma\gamma'.$$

As this supposes the linear vector operator to be given not by a single letter, but by several vectors, it must be regarded as entirely inadequate by any one who wishes to treat the subject in the spirit of multiple algebra, *i.e.* to use a single letter to represent the linear vector operator.

But my critic does not like the notations $|\Phi|$, Φ_s, $\Phi_\times$. His ridicule, indeed, reaches high-water mark in the paragraphs in which he mentions them. Concerning another notation, $\Phi \overset{\times}{\underset{\times}{}} \Phi$ (defined in NATURE, vol. xliii. p. 513), he exclaims, "Thus burden after burden, in the form of new notation, is added apparently for the sole purpose of exercising the faculty of memory." He would vastly prefer, it would appear, to write with Hamilton $m\phi'^{-1}$, "when m represents what the unit volume becomes under the influence of the linear operator." But this notation is only apparently compact, since the m requires explanation. Moreover, if a strain were given in what Hamilton calls the standard trinomial form, to write out the formula for the operator on surfaces in that standard form by the use of the expression $m\phi'^{-1}$ would require, it seems to me, ten (if not fifty) times the effort of memory and of ingenuity, which would be required for the same purpose with the use of $\frac{1}{2}\Phi {}^{\times}_{\times} \Phi$.

I may here remark that Prof. Tait's letter of endorsement of Prof. Knott's paper affords a striking illustration of the convenience and flexibility of a notation entirely analogous to $\Phi {}^{\times}_{\times} \Phi$, viz. $\Phi : \Phi$. He gives the form $S\nabla\nabla_1 \, S\sigma\sigma_1$ to illustrate the advantage of quaternionic notations in point of brevity. If I understand his notation, this is what I should write $\nabla\sigma : \nabla\sigma$. (I take for granted that the suffixes indicate that ∇ applies as differential operator to σ, and ∇_1 to σ_1, σ and σ_1 being really identical in meaning, as also ∇ and ∇_1.) It will be observed that in my notation one dot unites in multiplication the two ∇'s, and the other the two σ's, and that I am able to leave each ∇ where it naturally belongs as differential operator. The quaternionist cannot do this, because the ∇ and σ cannot be left together without uniting to form a quaternion, which is not at all wanted. Moreover, I can write Φ for $\nabla\sigma$, and $\Phi : \Phi$ for $\nabla\sigma : \nabla\sigma$. The quaternionist also uses a ϕ, which is practically identical with my Φ (viz. the operator which expresses the relation between $d\sigma$ and $d\rho$), but I do not see how Prof. Knott, who I suppose dislikes $\Phi : \Phi$ as much as $\Phi {}^{\times}_{\times} \Phi$, would express $S\nabla\nabla_1 \, S\sigma\sigma_1$ in terms of this ϕ.

It is characteristic of Prof. Knott's view of the subject, that in translating into quaternionic from a dyadic, or operator, as he calls it, he adds in each case an operand. In many cases it would be difficult to make the translation without this. But it is often a distinct advantage to be able to give the operator without the operand. For example, in translating into quaternionic my dyadic or operator $\Phi \times \rho$, he adds an operand, and exclaims, "The old thing!" Certainly, when this expression is applied to an operand, there is no advantage (and no disadvantage) in my notation as compared with the quaternionic. But if the quaternionist wished to express what I would write in the form $(\Phi \times \rho)^{-1}$, or $|\Phi \times \rho|$, or $(\Phi \times \rho)_s$, or $(\Phi \times \rho)_\times$, he would, I think, find the operand very much in the way.

J. WILLARD GIBBS.

On Secular Variations of our Rainfall.

IN studying the rainfall of this country, it is instructive, I think, to compare a number of curves for different places, and a long series of years, all smoothed by means of five year averages. In the case of places not too far apart, one may then recognise a common type amid some diversity of detail. But it is not easy to trace such "family likeness" between *e.g.*, curves for the west of Scotland and the east of England.

The east of England curves seem to conform to the general law affirmed by Brückner for the greater part of the globe, viz. cold and wet periods alternating with warm and dry ones at intervals of about 35 years; so that, taking recent years, there was, in most places, a rainy period between 1841 and 1855, and again between 1871 and 1885, while a dry period occurred between 1856 and 1870.

In the accompanying diagram are shown two east of England curves, one for East Anglia, giving mainly the rainfall for Dickleburgh, in Norfolk, continued for about 17 years by that of Norwich (according to *British Rainfall*), the other for Boston (from the same work). These curves, it will be noted, dip down from a relative maximum in the early years, 1843 and 1847, and rise again to maxima in 1877 and 1881.

Some rainfall statistics for Oviedo were recently given in the *Meteorologische Zeitschrift* (Feb., 1892, p. 71). This is, it may be well to state, a university town in the north of Spain, capital of the province of Asturias, and about 20 miles from the coast of the Bay of Biscay. Now, the smoothed curve of this place, from 1853, has a form distinctly opposite to those just considered (as the diagram shows[1]). It rises to a maximum in 1864, goes down to a minimum in 1877, after which it rises again, reaching, perhaps, another maximum in 1887.

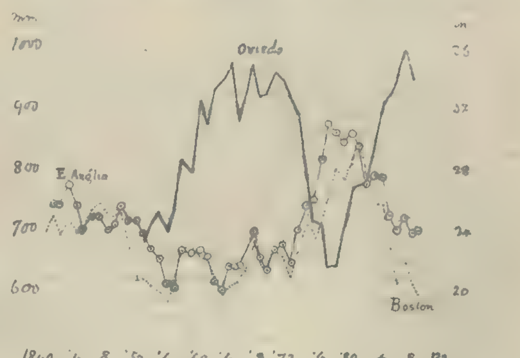
[1] The vertical scales, right and left, are not to be taken as equivalent.

This oppositeness in the variation of rainfall appears to merit attention. How is it to be explained?

One of the most interesting meteorological facts brought to light in recent years is, that the depressions which come over from the west do not take, as it were, a random course, but tend to follow, with more or less frequency, certain well-defined paths. The course of several of these paths has been indicated by Van Bebber, who has made a special study of the subject. Some of the paths are known to shift in the course of the year, having a different direction in midsummer from what they have in midwinter. And there can be little doubt, though the matter is still obscure, that the paths shift in successive years. The paths numbered IV and V by Van Bebber, are said to have shifted in the years 1879 to 1884-5 from a more maritime to a more Continental position, and Lang connects with this an observed variation in the rate of travel of thunderstorms in South Germany (see *Met. Zeits.*, Nov., 1891, p. [68], of *Literaturber*). Such shifting is very probably accompanied with variations of rainfall. Hellmann supposes this to be the reason why in Spain a year that is wet in the north-west is generally dry in the south-east, and *vice versâ*. We might, perhaps, roughly compare such variations to the case of a man watering a lawn with a garden hose, and directing the jet of spray now on one side, now on the other.

I do not know whether any suggestion of this nature is applicable to the case before us, or whether some other and better explanation may be forthcoming.

Oviedo is not, apparently, included in Brückner's data for estimating Spanish rainfall; and it is to be noted that he



regards the north of Spain as conforming to his thirty-five years law, while southern Spain is reckoned exceptional.

Brückner has two classes of exceptions: the "permanent," in which the curves are opposite to the normal (Ireland and the Atlantic islands being examples), and the "temporary," in which there is conformity to the rule, for a time; then, during some lustra, there come irregular variations. To this latter class are relegated south and middle Spain, Mediterranean France, West England, and Scotland. If Brückner's view regarding the north of Spain is correct, how comes it that the Oviedo curve has the character indicated, which is apparently that of the permanent exceptions?

In discussions on the subject of sunspot influence on weather one sometimes hears the opposite character of weather in different regions urged as a difficulty in the way of accepting such influence. Thus, in connection with a paper read by Mr. Scott to the Royal United Service Institution last year (*Journal*, May, p. 510) I find him remarking: "It is not possible to say whether or not the mere fact of our having very wet or dry weather is due to the sunspots, when our neighbours not very far off are having exactly the contrary. . . . Last summer everybody was abusing the weather because of its wetness. I myself was then living in the Black Forest, and we had four days' rain in eight weeks. Which of these conditions depended on the sunspots? Was it my fine weather or was it the rain here?"

With all deference to an excellent authority, and without offering an opinion upon the particular cases cited, it seems to me not impossible that the influence of the solar cycle might be manifested in an opposite succession of effects in different regions. Suppose, *e.g.* that in some region the rainfall in a long series of years varied, not as in the cases above considered, but in a certain regular correspondence with the sunspot curve; and in another region (perhaps further south) in opposite correspondence; also that these variations were traced to the shifting of a depression path. The opposite correspondence would obviously not be a good reason for denying sunspot influence, but rather corroborative evidence of such influence. Again, it will be admitted, I think, as conceivable that we might find certain great anticyclonic systems to vary in position or extent with the sunspot variations. Suppose, then, an anticyclone which lay over a region (*a*) at the time of minimum sunspots, were moved in a given direction, say northwards, so that it came to cover a region (*b*) at the maximum of sunspots and that it returned to *a* by the next minimum. In that case a place, *e.g.*, in the south part of region *a*, would have high barometer at minimum sunspots, while a place in the north part of region *b* would have low barometer. And at the maximum of sunspots, on the other hand, the two places would again have opposite conditions of pressure (to each other and to the first). These are some out of many aspects of the matter which seem to me to render doubtful the affirmation that if the solar cycle influences weather, it cannot produce an opposite succession of effects in different (even neighbouring) regions.

To revert, for a moment, to the shifting of depression-paths, might it not, in some cases, account for certain changes observed in the relative proportion of different wind directions? Suppose *e.g.* that, by the shifting of a path a little southwards, a place which has been for some years in its southern border comes to lie in the northern border, might it not thus come to have more easterly wind and less westerly? A. B. M.

The Non-Inheritance of Acquired Characters.

DR. WALLACE, in a letter which appeared in NATURE on July 20, asks for the opinion of naturalists as to the interpretation of certain facts bearing upon the question of the "Non-inheritance of Acquired Characters," and as I have given much thought to the subject I venture to offer my opinion.

In two papers published in *Natural Science*, vol. i. (1892), I set forth at some length a theory of heredity which has hitherto, so far as I am aware, met with no public criticism, and which I believe sets the question at rest, not by establishing the views of either of the rival schools associated with the names of Weismann and Lamarck respectively, but by showing that another interpretation is possible, and one which while fundamentally opposed to both of these makes it possible that there may be some truth hidden in the almost meaningless statements of the Weismannians and of the Lamarckians alike.

Till "heredity" is defined, and till we know exactly what we mean by "inheritance of characters" (be they "acquired" or "blastogenic"), it is useless to argue as to whether characters are "inherited" or not.

Is the word "heredity" an abstract noun, the name of a quality, a sort of magnified "family-likeness," or is it not? Those who write of heredity are too prone to speak of "heredity" as if it were a force or combination of forces producing an effect; as an "inherent tendency," to resemble parents or other ancestors which it is perhaps not unfair to compare to the "inherent tendency" of a watch to tell the time or of a weathercock to point to the south-west. There are those who even speak of it as being "latent" for a time and then, owing to some unknown cause, "springing into activity" anew and giving rise to what we call "atavism." Even "atavism" is not infrequently spoken of, as if it were of the nature of a force or combination of forces, comparable to a "latent tendency," which after lying "dormant" or "latent" for a time in a weathercock, suddenly springs into new activity and causes it to point as of old to the south-west.

It appears to me that if we once grasp the idea that "heredity" is the name of a quality, a particular kind of "likeness" or "similarity," and nothing else, we shall be saved from much useless discussion of propositions which are intrinsically almost, if not quite, meaningless.

Artemia salina is the collective name given to a large number of individuals which have certain characters in common. It would hardly seem to be necessary to suggest the probability that this possession of many characters in common is due to the action of Natural Selection; that each new individual possesses the characters in question solely by virtue of the fact that Natural Selection has led to the production of individuals possessing the power to produce, under given constant conditions, eggs, which by virtue of their constitution will develop under given conditions into adults possessing the characters which natural selection has *under those conditions* rendered nearly constant.

It has been found that this same constitution does not necessarily lead to the same series of developmental changes *under other conditions*, and that in strong brine the eggs develop into animals which, though capable of living and multiplying under those conditions, differ in form from the ancestral *A. salina*. This new form has no more right to rank as a species than has a "worker" bee whose adult form differs from that of its parent merely on account of certain conditions to which it is exposed during development.

It appears to me to be absurd to ask whether the "acquired characters" of the so-called *Artemia Milhausenii* are inheritable or not. Experiment has shown that the constitution of the species *A. salina* has so little changed that it still has the power to produce eggs which under one set of conditions develop into *A. salina* and under another set of conditions into *A. Milhausenii*. The average constitution of the species has not varied: it still produces ova which will develop into either *A. salina* or *A. Milhausenii*, according to the conditions to which it is exposed. If we look upon the species as a whole, it is not too much to say that it exhibits *no acquired characters*. If bred in strong brine the individuals of many generations are alike, having been moulded by like influences, intrinsic as well as extrinsic. If the extrinsic influences change, new individuals differ from the old ones, simply because the constitution of the individuals as well as that of the species is such that under the new conditions the developmental changes occurring differ from those which would have occurred under the old conditions.

Whether this is true of all species and under all conditions consistent with life and multiplication, or is not true of some, is a matter for experiment, and can never be decided by argument. The experiment has been made by nature, and also by man in the case of *Amblystoma*, and with a result in exact conformity with the result in the case of *Artemia*.

The experiment has also been made with *white mice* in Freiburg, and it has been conclusively shown that under constant conditions the characters of successive generations are constant. One element of the environment in one series of cases was Prof. Weismann armed with tools for amputation of the the tails of the young mice, *plus* a determination to amputate those tails. So long as this remained a constant factor in the environment, so long and no longer did the taillessness of the adult mice remain a constant character of the species.

The Texan species of *Saturnia*, so long as the exclusive supply of *Juglans regia* is a constant factor in the environment, may or may not have a constant group of characters. That is a matter for experiment; but innumerable experiments, called collectively "domestication," have shown that whatever effect changes of certain details of the environment—such as food—may have, the suspension of natural selection will in the long run lead to inconstancy of all those characters which are relieved from its restraining influence.

If anything has ever been rendered certain in biology by prolonged experiment and observation, it is the fact that specific characters are maintained constant *by selection and by that alone*. Long continued selection—natural or artificial—may produce a seeming constancy of characters (*which we call "heredity"* !), but in the long run this constancy will vanish when the particular selection which has induced it has been suspended for a sufficiently long period.

The discusssion upon the "Inheritance of Acquired Characters," though it has led to many valuable results, has been throughout little more than a quibble, for in the whole discussion, so far as I am aware, the meaning of the word "inheritance" has never been defined. Most of the disputants appear to use the term as the name for the action of a force or combination of forces, which some have called "heredity"—a force or influence—either simple or complex—of which it is perfectly safe to deny the existence. There is no such *thing* as heredity—heredity is only a quality, a likeness or similarity, and nothing more. That likeness of characters is simply and solely due to the likeness of the influences which have produced the like characters, and pre-eminent amongst those influences is natural selection, though *every* factor of the environment has also had its part to play. So long as those like influences—

extrinsic and intrinsic—remain like, so long and no longer do their effects remain constant. What effects a change in those influences may produce experiment and observation, and these alone can determine.

For thousands of generations certain characters, such as blindness and winglessness, and enormous size of head and of jaws, and complete absence of all power of multiplication either direct or indirect, either sexual or asexual, have remained constant in "soldier" termites. No soldier termite has any marked resemblance to any one of its ancestors. Yet each is like every other "soldier," and that likeness is "heredity." Its characters have not been "transmitted," for no ancestor ever possessed them. Like conditions in successive generations lead to like results, one of which is the production of a fairly constant proportion of neuter "soldiers" and "workers" devoid of any power of reproduction. Those "like conditions" include a constant, or nearly constant, structure of the males and females, albeit the polymorphism extends to these also. The recurrence of tho e like conditions has been determined by natural selection, and is still maintained by natural selection. To apply the term "transmission" in such a case would be not more absurd than in any other case, supposing the word to be used in its literal sense, for, though the soldier in every case derives its characters from a line of ancestors extending back to remote periods, not one ancestor in which line has possessed those characters; yet their geographical distribution at the present time shows that the characters of "soldiers" are of remote antiquity. This constancy of characters in many generations appears to be identical with the phenomenon called "inheritance."

Heredity then is a likeness of effects due to likeness in the causes producing them. The likeness of causes has been produced and maintained by natural selection acting under fairly constant conditions. "Inheritance" is a name given to the operation of an influence which has no existence in nature. The sooner we cease to use the word altogether the better it will be for our science.

"Inheritance of acquired characters" is a mere chain of words correlated with a chain of loose ideas, but not correlated with any natural objective phenomenon. To assert it as a fact is as futile as to deny it. C. HERBERT HURST.

Owens College, Manchester, July 26.

Echinocyamus Pusillus.

MAY I direct your attention to a rather serious error contained in the review of Théel's paper on *Echinocyamus pusillus*, which appeared in your number for August 3?

Your reviewer states that "not the least brilliant and far-reaching" of the advances in our knowledge of Echinoderm morphology, made in the year 1891, is the discovery by Brooks and Field of the primary bilateral symmetry "of the water-vascular system" of Asterias.

Had such a discovery been really made, it would no doubt have justified the epithet applied to it by your reviewer; but, in the first place it was not made, and in the second Metschnikoff long ago pointed out such a primary bilateral symmetry in the embryos of *Amphiura squamata*.

Field's paper, containing the results of his own and Brooks's work, appeared in the *Quarterly Journal of Microscopical Science* for 1892. In it he gives an account of the development of the larva of Asterias; but in the oldest stage which he describes *there is not as yet a trace of the water-vascular system.* He describes, it is true, in larvæ of a certain size a right as well as a left madreporic pore; but as all "echinologists," it is to be hoped, know by this time, the pore is primarily related to the cœlom, and only secondarily enters into connection with the water-vascular system. Further, Field distinctly states that cases of a double pore had been observed previously by continental zoologists, but regarded by them as pathological; and the chief point in Field's paper is the very probable theory put forward by him that such cases constitute a distinct stage in the ontogeny of the animal. E. W. MACBRIDE.

Zoological Laboratory, New Museums, Cambridge, August 5.

ON referring to my draft notes, which I happen to have kept, I find in place of the words "water-vascular system," quoted by your correspondent, "pore canal system"; and I do not deny that I should have done better had I transcribed them unchanged. I fail at the same time to see that the "error" complained of is, in its place, as serious as my critic would imply. No one who attempts to do his duty by the colossus of biological literature would fail to be familiar either with the work of the authors whom he cites, or with his own recent beginning in a kindred direction. Admitting the claims of one and all, the work of Field appeared to me to put the probability at stake upon a much firmer basis than that of his predecessors, and it was for that reason that I emphasised it. If I err not, a journalistic notice is not a thing to be hampered with names and details, especially when written with the dual object of directing attention to a really admirable monograph, and of endeavouring to promote an amicable spirit of brotherhood among workers in science, such as we to-day very much need. THE WRITER OF THE NOTICE.

The Supposed Suicide of Rattlesnakes.

THE letter of Mr. Edward S. Holden on this subject is extremely interesting. It appears that he, like other individuals who have imagined that they have witnessed the suicide of scorpions, has fallen into the error (so common in the interpretation of biological as distinguished from abiological phenomena) of stating his inferences and beliefs as though they were observations. The "instance which occurred before my eyes" (to quote his words, which remind one of the old herbalist, Gerard) was simply that of a snake biting itself when imprisoned in a jar of water. That the blow was "deliberate," "intentional," and of "suicidal purpose" is pure speculation—and nothing occurred before Mr. Holden's eyes to warrant his entertaining such a notion. Had Mr. Holden been aware that the poison of the rattlesnake has little or no effect upon another rattlesnake, nor upon the individual from which the poison is furnished, he would probably have been less ready to conclude that the bite was one of suicidal purpose. He would then perhaps have inquired as to the depth to which the bite penetrated into the tissues of the snake, and how far such a superficial bite as a snake can inflict upon a part of its own body is likely (in the absence of any poisonous action) to be seriously injurious to the snake.

In this case, as in that of the scorpion confined in a fiery circle (experimentally studied both by myself and by Prof. Bourne, of Madras, and reported on in the Proceedings of the Linnean Society and the Royal Society) the spasmodic struggles of an animal artificially confined and tortured, have been, as we clearly demonstrated, mistaken for efforts at self-destruction. The biting of its own body by the snake may be justly compared with the "biting the dust" attributed to men who die in hand-to-hand struggle, or to the biting of their own hand or arm by unhealthy children when suffering from a paroxysm of anger. E. RAY LANKESTER.

Oxford, August 11.

Imitation or "Instinct" by a Male Thrush?

ON the evening of July 19 a young thrush was caught in my conservatory and placed in a large outside aviary. The following morning I observed the parent birds feeding the young one through the bars with worms. In the same aviary there had been for more than ten years a male thrush which had been captured when quite young and had never been mated or troubled with family cares. On observing the parents of the young bird feeding their offspring he at once followed their example. On putting some bread and milk into the aviary he flew down, took up a piece and tried to induce the young bird to open its beak. At first the young thrush appeared to be afraid of accepting food from the foster-father, but after some persuasion it allowed itself to be fed with bread and milk, hemp seed, and other food. The parent birds were watching from the outside, and during the whole time occupied by the old male in feeding their progeny were also trying to introduce food through the bars The day after (July 21) the parent birds did not make any further attempt to introduce food, but contented themselves by watching their young one from a tree close at hand. If any of the house-cats approached the aviary the parents would at once give the alarm. In the course of another day or two they abandoned the young one entirely to the care of the old foster-father, who has proved quite worthy of his trust, as the young bird is now able to feed himself and is in a very thriving condition. The old male still insists, however, on giving it any delicate morsel he may find. This observation appeared to me to be of sufficient interest to record in your columns, as the old male bird certainly in this case learnt how to feed the young one by observing the proceedings of the parent birds. He had never reared any young ones of his own, and had never had any opportunity of seeing other families brought up in the aviary. E. BOSCHER.

Belle Vue, Twickenham, Aug. 1893.

Intrusive Masses of Boulder-clay.

THE letter of Messrs. Graham Officer and Lewis Balfour upon the glacial deposits of Bacchus Marsh suggests the desirability of uttering a word of caution against the assumption that boulder-clay intercalated between two beds of rock is necessarily of intermediate age. I have repeatedly observed *intrusions* of boulder-clay into the triassic sandstones of Lancashire and Cheshire, but never so striking an example as that described by Mr. Arthur R. Dwerryhouse in the current number of the *Glacialists' Magazine*. In his paper and the accompanying plate he shows how a series of glacial and triassic deposits were displayed in a trench in such a way as to give the impression that they were interbedded, sandstone being both below and above the glacial deposits. A minute examination established the fact that the drift deposits had been thrust in amongst the older rocks along a line of weakness due to the presence of a bed of marl. The intrusion had penetrated to a distance of *fifty yards* from the outcrop of the marl-bed.

I do not suggest that Messrs. Officer and Balfour have been misled by such an appearance, but merely warn geologists in general against falling into error.

We have heard much of late of floods and other catastrophes, even from geologists possessing a considerable intimacy with the phenomena of the British drift deposits. It would be interesting to learn in what way these injections of glacial sludge would be explained by the advocates of deluges.

A Peculiar Discharge of Lightning.

I SHOULD like to add to the many recent accounts of lightning discharges the following particulars of which I have not yet seen any published account.

On the afternoon of Wednesday, July 26, during a storm at about 5.30, a blue flame was observed by some of the inhabitants of Epping to approach and shatter the chimney of a house upon the hill, occupied by Mrs. Brown and family at the time.

An examination of the interior of the house shows the discharge to have passed chiefly by the bell wires, which are fused, down one corner of a room upon the upper floor, breaking the back of a chest of drawers near, and setting the wall in the vicinity on fire.

On the ground-floor the discharge seems to have taken two paths to earth, viz. down the corner of a front room by means of some metallic damp-proof paper, and in the kitchen adjacent by means of some wooden cupboards, the doors of which were much broken and thrown across the room.

Mrs. Brown, who was seated in the front room, states that a few seconds before the house was struck she noticed what appeared to be a darkened space, surrounded by a crimson fringe of flame in the corner (perhaps a brush discharge), and her son in the kitchen at the time testifies to having seen a similar thing previous to what appeared to be the bursting of the luminous mass, which occurred with a loud report, filling the house with smoke and the usual accompanying smell of ozone. The walls are much damaged, and the polarity of a small compass in a drawer of a sideboard nearest the path of discharge was reversed. I considered the apparent forewarning of the brush discharge of sufficient interest to justify this letter.

The Mean Density of the Earth.

IN a note in your issue of August 10, adding to the list of values for the mean density of the earth, which you gave on July 27, it is stated that Jolly and Poynting obtained the value 5·58. This is, I believe, the value obtained by von Jolly, but my final result, as published in the Philosophical Transactions for 1891, is 5·493.

In any account of recent work on this subject I think von Sterneck's experiments at Pribram and Freiberg deserve notice. These were made in the years 1882–5, and were pendulum experiments of the Harton Pit type. The method of comparing the times of swing of the pendulums below and at the surface was, I believe, quite new, and consisted in determining the coincidences with the same clock, which gave simultaneous half-second signals at the two stations by means of an electric circuit. The results unfortunately tend to confirm the conclusion which had, I think, been already drawn from Airy's work—that the mine method of experiment, though it may add to our knowledge of the constitution of the surface strata, is useless in determining the mean density of the earth.

Major von Sterneck's papers are published in the Proceedings of the Militär-Geographisches Institut of Vienna.

Pensarn, Abergele, August 12. J. H. POYNTING.

The Grouping of Stars into Constellations.

CAN you or some of your readers kindly give me an answer to the following questions, or tell me where I may obtain information on the subjects?

Did the Assyrians, Egyptians, Greeks, and Persians group the stars in the same manner into constellations? In cases where they did so were the constellations usually named by all the nations after the same animals?

How were the constellations, which we call after Greek heroes, named by Assyrians and Egyptians?

Do the different races of the present day, Chinese, Polynesians, Hindoos, Negroes, Americans, &c., each group the stars in a peculiar way?

If each race has its own plan of grouping the stars can we make use of this peculiarity in ascertaining the affinity of various races and nations? M. A. B.

Terriers Green, High Wycombe, August 11.

Numerous Insects Washed up by the Sea.

HAVE any of your correspondents mentioned the following fact? For the last two days, August 8 and 9, the shore at Dymchurch, Kent, and for more than two miles towards Hythe, was covered with countless quantities of winged ants washed to the shore by the waves. At low tide one sees three or four rims, so thick that each makes a black stripe, from two to three inches wide, running without interruption for more than three miles, and probably extending to a greater distance. We have had during these days winds from the north-east, very light on Tuesday morning, but strong since that.

Dymchurch, Kent, August 10. SOPHIE KROPOTKIN.

A Substitute for Ampère's Swimmer.

IN NATURE of July 27 Mr. Daniell gives a substitute for Ampère's swimmer. In Denmark we use the following simple rule given by Prof. Holten at least twenty years ago. The outstretched right hand is put in the current with the palm turned toward the magnet and the fingers in the direction of the current. Then the north-seeking pole will be moved in the direction of the thumb. HANNA ADLER.

Copenhagen, August 3.

A Correction.

IN my paper on "The Chatham Islands: their relation to a former Southern Continent," just issued among the Supplementary Papers of the Royal Geographical Society, vol. iii., there occurs a slip in the third and fourth lines from the foot of page 9, which I should feel obliged by your kindly allowing me to correct in your columns. My attention has been called to it by Prof. Newton, of Cambridge. In quoting from his and Sir Edward Newton's observations in the appendix to Captain Oliver's voyage of Leguat, as to the "now submerged Continent," of which Rodriguez, Mauritius, Bourbon, and Madagascar are, according to them, the existing fragments, I inserted the words "named *Lemuria*, by Dr. Sclater" after the word "continent." These words of mine should have occurred within square brackets, the absence of which was, I regret, overlooked in the proof. "Now the old land-connexion," writes Prof. Newton, "of the Mascarene Islands with Madagascar, of which we spoke as probable, is not at all necessarily the same thing as 'Lemuria,' which Mr. Sclater supposes to have reached some of the Malayan countries."

THE ASTRONOMICAL HISTORY OF ON AND THEBES.

II.

IN relation to the extract from Brugsch, given in the last article, to the effect that there was one series of monuments with its starting point in the Delta, it must be emphatically stated that the results obtained from these monuments, studying them from the astronomical point of view, leads to a very different conclusion. Instead of one series there are distinctly two, absolutely dissimilar astronomically, and instead of one set of temple-builders going up the river there were two sets: one going up the river building temples to north stars, the other going down building temples to south stars; and the two streams practically met at Thebes, or at all events they were very fully represented there.

The double origin of the people thus suggested on astronomical grounds may be the reason of the name of "double country," used especially in the titles of kings, of the employment of two crowns, and finally of the supposed sovereignty of Set over the north, and of Horus over the south divisions of the kingdom.[1]

With regard to the start point of the temple-builders who came down the river, there is no orientation evidence, for the reason that there is little or no information from the regions south of Naga. At Naga (lat 16° 18′ N.), Meroë (lat. 16° 55′ N.), Gebel Barkal and Nuri (both in lat. 18° 30′ N.), there is information of the most important kind, but beyond Naga there is a gap; but since important structures were erected at the places named in, I think, early times (3-4000 B.C.), it is probable that the peoples who built them stretched further towards the equator.

With regard to the southern limits of Egypt in the time of Thotmes, it is supposed that the south frontier Kali of the inscriptions is probably connected with Koloë in 4° 15′ N. lat. according to Ptolemy.[2]

The authority for the general statement I have made rests upon the probable dates I have found for the first foundations of the temples of both series (N. and S. stars) which I have investigated, and here I must re-state that in almost every case that foundation precedes the generally-received date, which generally has reference to a stone building; while in all probability the first structure was a brick shrine merely, and in support of this view I may state that the looking after ruined shrines was recognised as one of the duties of kingship.

"I have caused monuments to be raised to the gods; I have embellished their sanctuaries that they may last to posterity; I have kept up their temples; I have restored again what was fallen down, and have taken care of that which was erected in former times."[3]

Not only did Thotmes III. find the original temple of Amen-Rā built in brick, but he found the temple at Semneh in brick also, and he rebuilt it in memory of Usertsen III.[4]

I have prepared a table which it is not necessary to give in this place. I bring together the foundation dates I have found most probable, bearing the above and many other considerations in mind. The dates are, of course, only provisional, since local data are in many cases wanting. Where no information is forthcoming as to the height of the horizon visible along the temple axis, I have assumed hills 1° high.

The following general conclusions may be drawn from the table:—

I. At the earlier periods there are well-marked epochs of temple-building revealed by the table.

II. The temples to the north stars, α Ursæ Majoris and γ Draconis, begin in the Delta.

III. The temples erected to the southern stars (α Centauri and Phact) begin at Gebel Barkal, Philæ, and Thebes almost simultaneously.

IV. The first north star temples for the worship of Set and Ptah were erected between 5400-4200 B.C. The series is then broken till about 3500.

V. The first south star temples (Phact at the summer solstice and α Centauri at the autumnal equinox), begin about 3700 B.C.

VI. γ Draconis replaces α Ursæ Majoris at Denderah, and north star temples are for the first time erected in the south at Karnak and Dakkeh in 3500 B.C.

VII. For the first time about 3200 B.C., N. and S. star temples are built simultaneously.

VIII. After this the building activity is chiefly limited to temples to southern stars.

If we take Brugsch's dates, we find that the foundations of the greatest number of temples were laid about the time of Seneferu, Pepi, and the twelfth dynasty. The more modern kings founded few temples, their function was that of expanding, restoring, and *annexing*. Even Thotmes III. seems to have laid no new foundations except perhaps that of the Ptah temple at Karnak, and that is doubtful.

This after all is not to be wondered at. Three thousand years of observations at least had shown that the stars were not to be trusted to fix a festival day, and the true astronomical user of the ancient temples had quite passed away. Still the ancient shrines were there, what more natural then, than to embellish them? The priests, by insisting upon the vague year had reserved to themselves a perfect means of hiding all festival difficulties for once in 1460 years; the old star would rise on the proper day of the Egyptian month, although it would be no longer visible in the temple. Indeed it is extremely probable that we have here the real reason of the priestly action. They were not fools, and they could, one would think, have had no better reason than this.

The wonderful Hall of Columns called Khu-mennu (splendid memorial), in the temple of Amen-Rā, was dedicated by Thotmes III. not only to Amen-Rā, but to his ancestors. It is interesting to note who these were in the present connection. I give them with Brugsch's dates.[1]

	B.C.
Seneferu	3766
Assa	3366
Pepi	3233
The Antefs	2500
The most famous sovereigns of the twelfth dynasty	2433—2300
30 princes of the thirteenth dynasty	2233

Of these ancestors, the first limited himself to southern temples, the majority, built near Pepi's time, were south temples. The twelfth dynasty was more catholic.

The more we continue it, the more interesting does this inquiry into the north star temples as opposed to the south star temples become.

These considerations are not limited to the temples, they apply also to pyramids.

At Gizeh we find both temples and pyramids oriented east and west.

At Gebel Barkal, Nuri, and Meroë in Upper Egypt, we find both temples and pyramids facing south-east, and at the former place, where both exist together, we find well-marked groups of pyramids connected by their orientations with each temple.

In the following tables I give the values for Meroë, Nuri, and Gebel Barkal:—

It seems quite justifiable from the above facts to conclude that the pyramids and temples oriented S.E. and, as I hold, to α Centauri when it heralded the autumnal equinox, were not built by people having the same astronomical ideas, worships, and mythology as those who built at Gizeh due E. and W., and marked the autumnal equinox by the heliacal rising of Antares.[4] The only thing in common was noting an equinox, and so far as this goes we may infer that neither people dwelt originally in the Nile Valley, but came by devious ways from a country or countries where the equinoxes had been made out. J. NORMAN LOCKYER.

[1] For plans see "Lepsius," vol. ii. 133 and 134. A west variation of 8½° has been assumed.

[2] For plans see "Lepsius," vol. ii. 130. A west variation of 8½° has been assumed.

[3] For plans see "Lepsius," vol. ii. 125 and 127. A west variation of 8½° has been assumed.

[4] There is a point of great interest here It would seem from Captain Lyons' examination of the temples at Wady Halfa, which I make out to have been oriented to α Centauri, that when the two races were amalgamated in later times, both the stars to which I have referred as heralding the equinox were personified by the same goddess Selk

APPARATUS ILLUSTRATING MICHELSON'S METHOD OF OBTAINING INTERFERENCE BANDS.

IN the *American Journal of Science* for August, 1881, Captain Michelson described an ingenious method for producing interference bands, used by him in determining the relative motion of the earth and the luminiferous ether. Light from a lamp at a falls on a thinly silvered mirror b, where it divides into two rays—one, $b\,c$, reflected from the thinly silvered surface, is reflected back to b by the plane mirror c; the other ray traverses the glass plate b, and falls on the plane mirror d, whence it is reflected back to b. Here both rays reunite, and pass onward toward e. The mirrors d and c are silvered and polished on their front surfaces. By this means bands, similar to Newton's rings, are obtained between the mirror c and the reflection of d in b; the retardation of one ray with respect to the other being the length $bc-bd$; f is an unsilvered piece of plane glass, cut from the same piece as b, and placed in the ray $b\,c$, so as to compensate for the ray $b\,d$ passing twice through b; otherwise, owing to the dispersive power of the glass in b different wave-lengths of light in the ray $b\,d$ would be unequally retarded in comparison with the same wave-lengths in the ray $b\,c$. If the path $b\,c$ be now equalised in length with the path $b\,d$, and if, moreover, the piece of glass f be exactly equal and parallel with b, the central band will be black, owing to the ray

FIG. 1.

$d\,b$ being reflected from the rarer medium, whilst $a\,b$ is reflected from the denser medium.

Apparatus to show these bands can be easily and cheaply set up, and owing to the fact that an extended source of light may be used, they can easily be projected, and thus many interesting experiments shown to a large audience. The following is a description of a simple construction of the apparatus which I have found to work admirably.

All the parts are mounted on a piece of plate-glass ¼″ × 9″ × 12″. The two mirrors d and c, each two inches square, were silvered by the milk-sugar process, and afterwards polished with washleather and rouge in the ordinary manner. The mirror b was withdrawn from the silvering solution when only a thin layer had been deposited; no polishing was necessary. The layer of silver should reflect considerably more than half the light incident upon it, as thus the reflections from the unsilvered surface of b become relatively insignificant. Ordinary plate-glass was used in each instance.

Each mirror was attached vertically by pitch to a stand composed of two pieces of band brass soldered together at right angles, having three feet a, b, c (Fig. 2). In the case of the glasses b, f, and c (Fig. 1), a screw of pitch $\frac{1}{20}$″ was inserted in c (Fig. 2) as a rough adjustment for verticality of the mirror.

The mirrors b and f were maintained in position[1] by the conical foot a (Fig. 2) standing in a cylindrical hole in a blank which was stuck to the glass bed-plate by pitch, b resting simply on the surface of the glass, whilst the foot c stood in a V-groove in a brass blank, also stuck by pitch to the glass bed-plate. The fine adjustments required are for c (Fig. 1) a motion in the direction cf, and for d, adjustments in altitude and azimuth. These were respectively obtained by placing the two feet b and c (Fig. 2) (which should be rounded) of the mirror c (Fig. 1) in a long V-groove (a piece of angle brass was used),

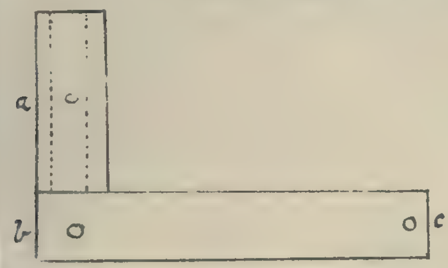

Fig. 2.—The dotted lines indicate the position of the mirror.

the third foot resting on the glass surface; the foot c was held against a screw passing, in the direction of the groove, through a brass blank soldered at the end thereof, which gave the longitudinal motion required for that mirror. By means of a lever of 18″ or so in length attached to it, a piece of steel wire, with a thread cut by means of stocks and dies of 40 to the inch, was found capable of adjusting to a quarter of a wave-length of light. The adjustments of the remaining mirror d (Fig. 1) were obtained by allowing the conical foot a (Fig. 2) to rest in a cylindrical hole, whilst the foot b rested on the glass as in the

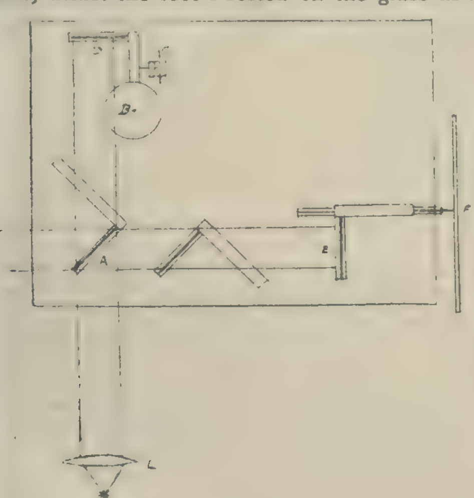

Fig. 3.

mirrors b and f (Fig. 1). The leg c (Fig. 2) was formed of a piece of steel wire with a screw thread cut as described above, with a large brass blank soldered to its upper end; this gave the adjustment in altitude. The adjustment in azimuth was obtained by holding the horizontal piece of band brass b c by means of a piece of elastic against the end of a screw of similar pitch to that last described, passing through a vertical pillar attached to the base-plate. The whole arrangement is shown in Fig. 3.

To avoid the effect of vibrations the whole may be supported on a block of stone, resting, in its turn, on hollow india-rubber balls; a plan adopted successfully by Dr. O. Lodge. When mounted in this manner the bands may be shown in a room possessing only an ordinary wooden flooring.

The bands are obtained as follows: A bat's-wing burner, or other source of white light, is placed at the focus of the lens L (Fig. 3) and arranged so as to illumine the mirror A. A card with a pinhole in it is then placed in front of the lens L, and, on looking in the direction M A, two images of this will be seen. By means of the screws B and C these two images are superimposed; and the distance A E having been adjusted by means of the screw and lever F and a steel scale, to be equal to A D, a sodium flame is placed in the focus of L and the pinhole card removed; the sodium bands will at once appear. By means of the screws B and C these are adjusted to a convenient width, and then, the bat's-wing burner having been replaced in the focus of L, the lever F is turned very slowly till the coloured bands appear. This can be done much more easily by placing a piece of platinum wire holding some sodium into the flame,

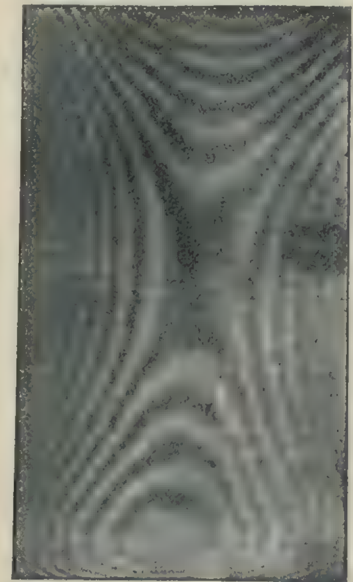

Fig. 4.—Photograph of interference band showing *cold* match.

when the bands due to the sodium will be faintly outlined on the white background, thus giving a guide as to whether or no you are turning the screw F too fast. The bands appear on the surface of the mirror E, and if an electric arc or a mixed gas limelight jet be substituted as the source of light, they can be projected on a screen so as to be visible to a large audience.

The forms of these interference bands, supposing each of the four pieces of glass to be perfectly plane and parallel, is given by Michelson (*Phil. Mag.* April 1882). The peculiar form of the bands obtained in my apparatus is shown in Fig. 4; this form is due to the curvature of the surfaces of the various glasses. A thin piece of glass or a soap film may be introduced into one of the paths and the displacement of the bands exhibited. But perhaps the prettiest experiment is to introduce the glowing end of a match into one of the rays. Suppose this ray to be A E (Fig. 3); then the appearance presented is exhibited in Fig. 5, where the bands are seen to curve round the end of the match as if it were pushing them inwards. A cold body, such as a piece of copper wire, cooled in a freezing mixture, has an opposite effect, attracting the bands into it. These effects are, of course, due to the heating or cooling of the air near the hot or cold body. Now it will be found on slowly turning the

[1] For some remarks on the general principles of these "geometrical slides" and "clamps," see Thomson and Tait's "Nat. Philosophy," part i. p. 150.

screw F (Fig. 3) so as to shorten the path A E that the bands at the side move in toward the centre, the opposite being the case on lengthening the path A E. Therefore heating the air (*i.e.* rendering it less dense) has the same effect as shortening the path (*i.e.* it accelerates the motion of the light passing along it), whilst

FIG. 5.—Photograph of interference bands sh wing effe:t of introducing glowing end of match.

cooling the air (rendering it denser) has the opposite effect; which demonstrates very simply the truth of the undulatory as opposed to the emission theory of light; for on the latter theory the exact reverse would be the case.

EDWIN EDSER.

THE AUGUST METEORS, 1893.

THE Perseid shower, though it cannot rival periodical displays such as the November Leonids and Andromedes when at their best, is certainly of equal interest, for it forms a tolerably rich display every year, and continues active during several weeks from a radiant which has a comet-like motion of about 1° R.A. per day eastwards. A vast number of observations have been made during the last half-century, but it must be confessed that we have by no means completed our investigation of this remarkable stream. Nor have we gained a thorough knowledge of the numerous and fairly prominent minor showers which contribute to render this epoch the most significant and the most interesting period of the year to the meteoric observer.

Either moonlight, or cloudy wet weather, prevented my obtaining any observations at the latter part of July this year, and it was not until August 4 that I commenced work. Moonlight was, however, pretty strong, and in a watch of about half an hour I only saw four meteors, including one typical Perseid from a radiant at about $36^\circ + 56^\circ$.

On the following night, August 5, the sky was much clouded, but between 10h. 15m. and 11h. 45m. I saw, in clear spaces, twelve meteors, of which four were Perseids, indicating a radiant at $39^\circ + 55^\circ$. The brightest meteor seen was at 11h. 3m., but it appeared behind thin cloud in the northern sky. It was fully equal to a 1st mag. star, and left a bright streak along its path from $17\frac{1}{2}^\circ + 76^\circ$ to $219^\circ + 78^\circ$. This was not a Perseid, the direction of flight being from near γ Andromedæ.

The nights of August 6 and 7 were cloudy and no observations could be secured.

On August 8 the sky cleared and I counted 36 meteors in the two hours from 10h. 50m. to 12h. 50m. There were 12 Perseids amongst them and the radiant was well defined at $41^\circ + 56^\circ$. At 11h. 25m. a fine Perseid about equal to Jupiter flashed out in the region of Polaris and left a streak of nearly 20 degrees along its course.

August 9 proved fine, but lightning was extremely frequent and vivid during the whole night, and considerably interfered with the observations. It proceeded from clouds low in the east and north quarters, but apart from that the firmament was very clear. The day had been one of excessive heat, the maximum shade temperature being 84°; the lightning which followed it may be said to have been in constant play during the night, one flash succeeding another with little intermission. The effect as it burst through the broken clouds and lit up their borders was very beautiful and so striking as to distract attention from the far less imposing features of the meteor shower then in progress. In the $2\frac{1}{2}$ hours' interval between 11h. 30m. and 14h. I managed, however, to observe 45 meteors, including 20 Perseids from a radiant which I determined as follows:—

h. m.	h. m.	°	
11 30	to 12 0 ...	42 + 56 ...	4 meteors.
12 0	to 13 0 ...	43 + 57 ...	9 ,,
13 0	to 14 0 ...	43 + 57 ...	7 ,,

Adopting the mean centre as at $43^\circ + 57^\circ$, I think the position may be considered a very accurate one for the date. I saw no exceptionally brilliant meteors during the night, though several of the 1st mag. were recorded, and the Perseids struck me as being fainter than usual. Most of them traversed swift short paths not very far from the radiant, so that the position of it could be determined very satisfactorily Mr. Booth of Leeds informs me that he found the Perseid radiant at $43^\circ + 57^\circ$ from 15 meteors of this shower observed on August 9. This positlon is identical with that found at Bristol on the same night.

On August 10 the sky proved variable, but it was pretty clear at times before midnight and overcast afterwards. Between 11h. and 12h. I noticed 21 meteors, of which 14, or two-thirds of the whole, were Perseids, but clouds interrupted work during a part of the time. After 12h. it was not found possible to continue the work with any further prospect of success, as clouds had obliterated all but a few 1st mag. stars. The Perseid radiant was now found at $45^\circ + 57^\circ$, which agrees with the usual position on the date of maximum. As to the character of the radiation on this and previous nights, it was fairly definite and exact, and limited to an area of 2° or 3°. In point of activity I regarded the shower as disappointing on the 5th, 8th, and 9th, but from what I saw on the 10th, and considering the unfavourable circumstances prevailing at the time, the display was a tolerably conspicuous one. I recorded several bright meteors on the 10th, and, as they may possibly have been seen elsewhere, the times of apparition and observed paths are given below:—

h. m.	Mag.	From α δ (° °)	To α δ (° °)	Radiant.	Notes.
11 0	1	1+11	26+19	304−14	Slow.
11 21	1	331+38½	317+23½	Perseid	Swift, streak.
11 24	1	325+29	314+15	Perseid	Swift, streak
11 43	♀	42+55	40+53½	Perseid	Slow, b. streak.
11 56	♃	140+84½	230+70	Perseid	Swift, streak.

On August 11 the sky was overcast.

On August 12 it was partly fine before 13h., but by no means favourable for this class of work. I counted 24 meteors, including 7 Perseids with radiant at $48^\circ + 57^\circ$.

On August 13 the conditions had greatly improved, and after midnight there was not a cloud in the sky. Watching for $3\frac{1}{2}$ hours I recorded 43 meteors and found the Perseid shower still visible from a radiant at $48^\circ + 57^\circ$ (8 meteors). No exceptionally bright meteors were seen, but at 13h. 5m. one about equal to Jupiter fell from

$338\frac{1}{2}^\circ+27^\circ$ to $347^\circ+19\frac{1}{2}^\circ$, its radiant being very probably at $271^\circ+48^\circ$ near the head of Draco.

On August 14 the atmosphere was unusually clear, and during the four hours from about 10h. 15m. to 14h. 15m. I observed fifty-six meteors. The Perseid shower was still distinctly visible, and the meteors pretty bright. From seven accurately observed paths a very good radiant was obtained at $49^\circ+57^\circ$. There was also a well-defined shower of streak-leaving meteors from Camelopardus at $61^\circ+59^\circ$, and these, if confused with the Perseids, would have given the latter radiant a very diffused appearance. On this and the preceding nights I saw many Cygnids and Cepheids from radiants at $292^\circ+53^\circ$ (sixteen meteors) and $311^\circ+62^\circ$ (fourteen meteors), and this pair of showers formed by far the most important of the minor displays of the epoch. I had in previous years detected the Cygnids, but never remember to have seen the shower of Cepheids on such activity.

On comparison of my Perseid radiants deduced, on August 5, 8, 9, 10, 12, 13 and 14 it will be seen that they exhibit an easterly movement in satisfactory agreement with my observations in preceding years. This remarkable displacement of the radiant may now almost be regarded as "an old story" but it will always remain a very significant and interesting feature of the shower both from an observational and theoretical standpoint. The motion of the radiant amongst the stars may be nearly as easily and certainly observed by an experienced and precise observer as the motion of a comet. The circumstances are different of course, for a radiant is simply an apparent position and not a visible object, but trustworthy observations define this position with considerable exactness, though it is impossible to eliminate all the sources of error.

Mr. Corder, at Bridgwater, informs me that on August 10, before 14h. he counted 129 meteors, but he regarded the display as rather a poor one. The mean position of the radiant was at $44^\circ+57\frac{1}{2}^\circ$, but he considers that it shifted from $40^\circ+56\frac{1}{2}^\circ$ to $47^\circ+58\frac{1}{2}^\circ$ during his observation.

Mr. Corder, watching until 15h. on August 13, counted 77 meteors, but he says the Perseids had almost ceased, and gave an uncertain radiant, but such as it was could be located near the stars B and C Camelopardi. He found a very active and well-defined shower of Cygnids from the point $293^\circ+50^\circ$. W. F. DENNING.

CHOLERA AND ARTICLES OF DIET.

ALTHOUGH in by far the larger number of cases the distribution of cholera has been traced to the use of impure water, yet there are a few authentic instances on record of its dissemination by means of various articles of diet, such as milk, fruit, salad, whilst Kossel and Steyerthal quite recently report two cases (*Deutsche med. Wochenschrift*, 1892) in which its communication was traced to bread and butter. It becomes, therefore, not only of interest but importance, to ascertain what is the vitality of the cholera organism when purposely brought in contact either superficially or incorporated with various articles of food. Researches in this direction have been undertaken from time to time by various investigators, Babes, Celli and others, whilst Dunham's experiments published in the *Medical Record* for 1892 are amongst the most recent and exhaustive on this subject. This author found that cholera organisms purposely introduced on to salad leaves and placed in a covered dish and kept at the ordinary temperature of a room, retained their vitality for five days, on cooked cauliflowers for from six to ten days, and on the same vegetable uncooked for thirteen days. On a sliced strawberry they did not survive more than twenty-four hours.

Some important contributions to our knowledge of this subject have been made by Friedrich, and are brought together in an elaborate memoir, "Beiträge zum Verhalten der Cholerabakterien auf Nahrungs und Genussmitteln" published in the *Arbeiten a. d. Kaiserlichen Gesundheitsamte*, vol. viii. 1893, p. 465.

The range of materials investigated is very extensive, upwards of fifty different articles being specially studied in this respect, including numerous kinds of fruit, several vegetables, besides milk, tea, coffee and cocoa, also particular descriptions of beer and wine, whilst amongst the miscellaneous materials examined may be mentioned caviar, biscuits, bonbons, tobacco, and snuff!

In the majority of cases the bacilli were not only rubbed on to the surface of the various fruits and vegetables, but were also inoculated on to slices, so that the effect on the bacillus of the *composition* of a particular fruit or vegetable could be ascertained. When simply exposed on the exterior of a given material, the vitality of the bacillus depends chiefly on the degree of moisture which is present in its environment, this organism being specially characterised by its rapid destruction in dry surroundings, but when brought in contact with the juices it is the proportion of fruit acid and sugar present which primarily determine its behaviour. The cholera bacilli are very sensitive to acid, and hence their destruction on most slices of fruit in from one to six hours.

Thus when inoculated on to slices of bright red very juicy and sour cherries, the bacilli were annihilated in three hours, whilst when simply rubbed on the surface and kept in a moist atmosphere they were still alive at the end of five days. On the other hand, when thus treated and exposed to the ordinary air of a room, the bacilli could not be found after twenty-four hours, whilst when placed in the direct sunshine their vitality was limited to one hour and a half.

But even on slices of fruit containing a much smaller amount of acid, such as pears, the vitality of the cholera organism was not much prolonged, and the reason for this must be sought in the fact that, when grown in solutions containing sugar, this organism produces acid, and the acid thus produced impedes its further development and destroys its vitality.

On vegetables such as cucumbers, cauliflowers, cabbages, the cholera bacillus maintains its existence for several days; thus on spinach leaves preserved in a damp atmosphere, the bacilli were still present after twelve days, and even when exposed to the ordinary air of a room they did not disappear until after six days.

As regards the behaviour of the cholera organisms in tea it is interesting to note that in a 3 per cent. infusion of black Chinese tea they are destroyed within twenty-four hours, whilst in a 4 per cent. infusion no trace of them could be found at the end of sixty minutes.

Friedrich has confirmed the results of other investigators on the bactericidal properties of coffee, finding two hours' immersion in a 6 per cent. infusion of this material sufficient for the destruction of these organisms.

In various kinds of beer, Munich, Pilsener, and Lager, they could not survive more than from one to three hours, but still more rapid was their extinction in white and red wine, for five minutes after their introduction they could no longer be found in the former, whilst in the latter their vitality did not exceed twenty minutes.

From the numerous investigations recorded it is obvious that during any epidemic of cholera the consumption of uncooked fruit and vegetables should be avoided, or that at any rate precautions should be taken to ensure their sterility by careful cleansing or by the removal of the rind or skin where possible.

G. C. FRANKLAND.

NOTES.

MEN of science throughout the world will be glad to know that the honour of knighthood has been conferred upon Dr. Joseph Henry Gilbert, F.R.S., who has been associated for more than fifty years with Sir J. B. Lawes in the agricultural experiments conducted at Rothamsted. British and foreign academies and learned societies have long recognised Dr. Gilbert's claims to distinction, and have bestowed upon him various marks of approval. We are glad now to be able to record that his scientific work has been officially recognised.

PROF. MAX MÜLLER has received from the Sultan of Turkey the gold medal of the Order of Merit, the highest honour in the Sultan's gift.

ZOOLOGISTS will learn with regret that Mr. George Brook, lecturer on embryology to the University of Edinburgh, died suddenly at Newcastle on Saturday night last. His death is a loss to zoology and to those who knew and appreciated him.

THE *Times* announces the death of Rear-Admiral T. A. Jenkins—one of the ablest officers of the U.S. Navy—at the age of eighty-two. In 1846 he prepared a report on the lighthouse systems of Great Britain and the continent. Shortly afterwards he assisted Prof. Bache in making some meteorological and hydrographical observations, and in determining deep-sea temperatures in the Gulf Stream, the vessel in which the investigations were carried on being built under his supervision. In 1852 he was appointed naval secretary of the Lighthouse Board, and from 1869 to 1871 was secretary of the Board. He was also for some time Chief of the Bureau of Navigation.

THE Franklin Institute has awarded a medal and a premium of twenty dollars, in accordance with the legacy of John Scott, of Edinburgh, to each of the following gentlemen:—Dr. Adolph Frank, Charlottenburg, Germany, for a composition of infusorial earth as adapted for filtering purposes; Frank Reddaway, Manchester, for his invention of camel-hair belting; Henry L. Bridgman, Blue Island, Illinois, for his invention of an ore sampling machine; and S. H. La Rue, Trenton, N.J., for his improvements in stoves. An Elliot Gresson medal has been awarded to Frederick E. Ives, Philadelphia, for his system of colour photography known as heliochromy. Any objections to these awards, or evidence of want of originality of the inventions named, should be lodged with the secretary of the Institute before October.

A REUTER'S telegram, dated August 11, reports that a violent shock of earthquake was felt on the previous evening in the small coast town of Mattinata. It was followed during the night by other shocks of less violence, which were felt also at Monte Sant', Angelo, Manfredonia, and Rodia—all towns on the shores of the Adriatic. Later information states that all the buildings in Mattinata were more or less seriously damaged by the earthquake, and great cracks were caused in the walls of the houses. Three persons were killed and four injured, while others were shaken or bruised. The island of Stromboli experienced a sharp shock, followed by an unusually violent eruption of the volcano.

THE Iron and Steel Institute will hold its twenty-fifth autumn meeting at Darlington, from September 26 to 28 inclusive, when several important papers will be read. Prof. Roberts-Austen, F.R.S., will contribute a paper on the influence of the rating of the rupee on the world's iron trade; Mr. H. Bauerman will discourse on the "Metallurgical Exhibits at the World's Fair"; and Mr. Kupelwieser will communicate a paper on the recent developments of the steel industry in Austria. A number of other subjects of technical interest will also be discussed. The members will have the advantage of visiting the numerous iron and steel works in the vicinity of Darlington, and arrangements have been made for excursions to Barnard Castle and Raby Castle.

THE Board of Agriculture have been requested to draw the attention of fruit growers to an international exhibition, to be held by the Russian Society of Fruit Culture, under the patronage of the Czar, at St. Petersburg, in the autumn of 1894, with the object of showing the present condition of the cultivation of fruit and vegetables, of viticulture, of the cultivation of various special plants, and the manufacture of their products. A congress of pomologists will be convened simultaneously with the exhibition. The exhibition will comprise sections dealing, among other matters, with horticulture implements and appliances, and technicality of production, and also literary, scientific, and educational accessories, collections, plans, &c. Detailed regulations of the exhibition and programmes of the various competitions will be published and distributed towards the end of this year. Persons interested in the progress of horticulture and pomology, both in Russia and other countries, are invited by the Russian Government to take part in this international exhibition and congress. Applications for further information should be addressed to the offices of the International Exhibition of Fruit Culture, Imperial Agricultural Museum, Fontanka 10, St. Petersburg.

SERIOUS floods have occurred in Galicia (says Reuter's agency) and they are exceeded in their gravity by disastrous inundations which have visited Saras and Ung, two northern countries of Hungary. The damage done in these districts is immense, and there has been serious loss of life. According to the latest accounts, the waters are now receding. Dispatches from Lemberg describe the havoc that has been wrought in the valleys beneath the Carpathians by the persistent rainfall. The rivers Dniester, Stryi, San, and Dunajec have overflowed their banks, causing great damage, especially in the districts of Zydaczow, Stryi, Przemysl, and Rimanow. At Turka twenty-two houses have been destroyed by the floods or struck by lightning, and many persons lost their lives.

DURING the past week the heat has been excessive in the midland and southern parts of England; it reached or exceeded 80° at Greenwich Observatory on eight successive days from the 8th instant, which is the longest period this summer during which such high temperatures have been recorded. On Wednesday, the 9th instant, and on Monday and Tuesday last, the temperature exceeded 85° in several places, and reached 89° in the neighbourhood of London on the latter day. On the 9th and 10th this exceptional heat culminated in severe thunderstorms in most parts of the country; in Ireland the storms and rainfall were very heavy, the amount of rain measured in the north of Ireland during the week ended the 12th instant being ·8 inch above the average. The heat on the continent has been much greater than in this country; the shade maximum at Rochefort in France reached 106° on Monday last.

DR. W. DOBERCK has communicated to *Hansa* of July 29 and August 5 an interesting article on the typhoons of the China Sea, a subject of which he has made a special study, and for the collection of the necessary materials his position as director of the Hong Kong observatory offers many advantages. So long ago as September, 1886, he communicated to the *Hong Kong Telegraph* a paper on the law of storms in the Eastern Seas. The present article embodies the facts there set forth so far as they relate to the subject in question, together with the results of the experience subsequently gained. The typhoons, like the hurricanes of the West Indies and other parts, generally give premonitory signs, such as the motions of cirrus clouds, the swell of the sea, and motion of the barometer, but there appears to be some difficulty in determining whether depressions will result in ordinary gales or in typhoons, and it is essential to determine quickly how a ship lies with respect to the advance of the centre of the disturbance. In these and other details which are of primary importance to the seaman navigating the China Seas, the information contained in the paper will be very useful.

THE report of the chief of the United States Weather Bureau for the year 1892 has recently been received, and shows that much attention has been given to the improvement of weather forecasts, the result being a success of 82·9 per cent. in the combined predictions of weather and temperature for twenty-four hours in advance. Until recently the issue of predictions was restricted to the Washington office, but now a number of competent observers make forecasts for their immediate vicinity. In order to render this service as efficient as possible, telegraphic reports are received when considered necessary from several of the West Indian islands. Various important investigations have recently been published, and at present the subject of the rainfall of the entire country is under discussion. The policy of the Bureau favours the establishment of high-level stations, and the observatory at Pike's Peak has been reopened; advantage has also been taken of one or two balloon ascents to obtain observations made in free air. Every effort is being made to advance the science of meteorology; the entire territory of the United States is now covered by local weather services with the exception of Alaska, and the weekly and monthly reports issued by them contain tables of meteorological data and discussions of great value to immigrants, invalids and to men of science generally. The *Monthly Weather Review*, issued by the Central Bureau, is a highly creditable work, prepared from the reports of upwards of 2600 observers. We also observe that frequent applications are made to the Bureau for climatological statistics, and that these are generally satisfied without expense to the applicants. The number of such applications during the year amounted to over 500; this fact alone is sufficient to show the liberal policy of the Bureau.

SOME elaborate investigations on the disinfecting powers of hypochloride of soda, chloride of lime, and peroxide of hydrogen have been recently published by Chamberland and Fernbach in the *Annales de l'Institut Pasteur*, June, 1893. When these materials were employed at a temperature of from 40–50° C. and higher, their action was invariably more rapid than when they were used at the ordinary temperature, thus affording a striking confirmation of Heider's experiments on the greater efficiency of disinfectants at higher temperatures, reference to which was made in NATURE for June 15. Micro-organisms in dry surroundings were found far more capable of resisting the action of these disinfectants than when exposed in a moist condition, that whereas in the latter case they were destroyed in a few minutes, in the former they defied an exposure of several hours, even to hot disinfectants. If, however, such dried germs be subjected to one hour's immersion in water they lose their power of resistance, for on the subsequent application of the disinfectant they succumb rapidly. These authors insist, therefore, on the importance of first spraying the walls of a room with water before commencing their disinfection. In conclusion a solution of chloride of lime (prepared by extracting one part of chloride of lime with ten parts of water and diluting the clear extract with ten times its volume of water) is recommended as an exceedingly efficient as well as economical disinfectant for practical purposes.

AN interesting example of the degree of resistance to high temperatures exhibited by some micro-organisms has lately been published in the *Centralblatt für Bakteriologie*, May 17, 1893. Whilst preparing nutritive gelatin-peptone in the usual manner, Heim found that, despite all precautions of sterilisation &c., numerous yellow or reddish-yellow centres subsequently appeared in the culture material. On isolating out these colonies and further studying them, these growths were ascertained to be derived from two spore-producing bacilli which had resisted the usual 10–20 minutes' exposure to steam on three successive days. On further studying these organisms it was found that one of them required three hours' continuous steaming before being destroyed, whilst the other was not annihilated until this had been prolonged for seven hours. These extremely hardy spores were traced to the leaf-gelatin employed, and as in many respects they resembled certain soil-microbes, Heim supposes that in some manner or other during its preparation the gelatin must have come in contact with soil. Still more recently a cladothrix has been found in water which, on account of its ability to resist high temperatures has been called *Cladothrix invulnerabilis* (*Centralblatt f. Bakteriologie*, vol. xiv. p. 14). It was still endowed with vitality after having undergone six successive exposures to ordinary intermittent sterilisation at 100° C.

M. LOUIS BOUTAN has succeeded in taking submarine photographs under various conditions, by a method described in the *Comptes Rendus*, No. 5. A camera constructed for several successive exposures was enclosed in a metal box provided with plane-parallel glass windows mounted in copper rings. The apparatus was mounted on a heavy stand provided with weights, so as to give it a steady footing on the sea bottom. Near the shore, in depths not exceeding 1 or 2 m., the camera could be placed in position without the necessity of the observer entering the water, and negatives were obtained by direct sunlight in about 10 minutes. With an exposure of 30 minutes negatives could be obtained at depths of 6 or 7 m., the apparatus being put up by a diver. The best images were obtained by placing a blue glass in front of the lens, but even the best showed a want of depth which could only be relieved by using a very small diaphragm. This difficulty would disappear if the lenses were adapted to submarine work to begin with. Pictures of the sea-bottom were also obtained instantaneously during a storm by means of a flash-light, consisting of an alcohol lamp fed by a reservoir of oxygen. Magnesium powder was projected into the flame by pressing a rubber ball. The depth at which these photographs can be taken is at present limited to that which can be attained by the diver.

THE absorption of light by platinum at different temperatures is discussed in a highly interesting paper recently communicated to the Accademia delle Scienze di Torino by Dr. G. B. Rizzo. He succeeded in obtaining transparent films of platinum produced under such conditions as to exclude the possibility of oxidation on raising the temperature. The apparatus employed consisted of two glass cylinders joined by a thin tube. Another tube was soldered to the middle of the latter, and connected with an air-pump and a reservoir containing nitrogen. The tubes were filled with nitrogen several times, and exhausted, so as finally to contain a rarefied atmosphere of nitrogen. One of the platinum electrodes was partly encased in glass, and connected with the negative pole of a Rhumkorff coil excited by six Bunsens, the other electrode being connected to the positive pole. Under these conditions the negative pole was volatilised and deposited as a thin film upon the walls of the glass cylinder containing the electrode. The glass cylinder was then disconnected by filling the apparatus with nitrogen to atmospheric pressure, melting the thin tube under the blowpipe, and drawing it out to a rod to be broken off. The platinum electrode was bent out of the way by melting its glass sheath, and the result was a cylinder of glass containing a fine deposit of platinum and filled with nitrogen. This cylinder was placed in an iron cylinder in a small gypsum furnace, and heated by a spiral tube of small gas jets. Light was transmitted through windows in the iron tube, and a Krüss universal spectroscope was used to compare the spectra transmitted through the glass and platinum, and through the glass only. The temperatures were measured by the calorimetric method. After allowing for the various reflections undergone by the light, it was found that as the temperature increased, the transparency of the film increased, especially in the more refrangible region. It may be added that this phenomenon, if found to hold generally, establishes a new correlation between light and electricity, the increase of electrical resistance of a conductor being accompanied by an increase of transparency.

THE alternate current supplied by the Innsbruck Central Station has been utilised by Dr. G. Benischke for the purpose of investigating the dielectric constants of some solids by the method of Gordon as improved by Lecher. This current charged the condenser positively and negatively at equal intervals, thus avoiding residual effects of all kinds. In order to obtain greater sensitiveness the alternate current was transformed to higher differences of potential by means of an induction coil. It was found that the dielectric constant is independent of the strength of the field in the condenser, and hence also that there exists no perceptible conductivity in the dielectric. The constant of paraffin was found to be 1·89, of ebonite 2·03, of sulphur 2·42, of common glass 4·17 to 4·52, of plate-glass 3·85.

WE have received the supplement to the calendar of the Royal University of Ireland for the year 1893. It contains the papers set at the University's examinations during 1892.

THE report of the fourth meeting of the Australasian Association for the Advancement of Science, held at Hobart Town, Tasmania, in January, 1892, has just reached us. It is edited by Mr. A. Morton.

THE *Midland Naturalist* contains an address delivered by Mr. W. H. Wilkinson, President of the Midland Union of Natural History Societies, on "The Life-History of the Diamond-Back Moth" (*Plutella cruciferarum*). We note that at the annual meeting of the Union on July 11 it was decided to discontinue the publication of the journal.

MESSRS. CROSBY LOCKWOOD AND SON will shortly publish "The Miner's Handbook," compiled by Prof. Milne, F.R.S., of the Imperial University of Japan. The volume is of especial interest on account of the fact that it is being printed under the author's direction at Tokio.

A CORRESPONDENT, "H. K. R.," writing from Victoria, Australia, with regard to a letter in our issue of March 30, refers us to another and in some respects simpler rule for finding the day of the week which corresponds to any given day of the year, to be found in Dr. Charles Hutton's "Mathematical Recreations," published in London in 1803.

THE U.S. Department of Agriculture has just issued a systematic and alphabetic index to new species of North American Phanerogams and Pteridophytes published in 1892, by Miss Josephine A. Clark. The index forms the seventh number of the third volume of contributions from the U.S. National Herbarium.

DR. MCALPINE has prepared a report for the Victoria Department of Agriculture on a poisonous species of Homeria found near Melbourne, causing the death of cattle feeding upon it. The species is *Homeria collina*, Vent.—var. *Miniata*, commonly known as Cape Tulip. There is evidence that it is fast spreading over the Colony, and strenuous measures will have to be taken to eradicate it.

WE have received the following excerpts from the Proceedings of the United States National Museum: Catalogue of the crabs of the family Maudæ in the U.S. National Museum; list of Diatomaceæ from a deep-sea dredging in the Atlantic Ocean off Delaware Bay, and scientific results of explorations, by the U.S. Fish Commission steamer *Albatross;* also notes on Erian (Devonian) plants from New York and Pennsylvania.

THE Memoirs and Proceedings of the Manchester Literary and Philosophical Society (vol. vii. No. 2) contains the second part of Prof. W. C. Williamson's General, Morphological, and Histological Index to his collective memoirs on the Fossil Plants of the Coal Measures. Prof. Harold B. Dixon, F.R.S., contributes a long paper on the "Rate of Explosions in Gases," and in collaboration with Mr. B. Lean, one on the "Length of Flame Produced by the Explosion of Gases in Tubes."

A COPY of Prof. C. V. Riley's presidential address on "Parasitism in Insects," delivered before the Entomological Society of Washington in 1892 has just reached us. It goes to show that "the parasitic forms and the parasitic habit have appeared late in the history of insect evolution on the globe." A number of papers by Prof. Riley on various entomological subjects have also been received. Among them is one on the habits and natural history of the Ox Bot-fly, *Hypoderma bovis*, in the United States. This has hitherto been supposed to be the common species of both America and Europe, but Prof. Riley finds that the species has not been observed and recorded in North America, hence he considers its presence as merely conjectural. The American species is *Hypoderma lineata*, Villiers, and it seems probable that when the life history of the European *H. bovis* has been worked out it will be found to coincide with the American Bot-fly as described by Prof. Riley.

A NEW mineral of exceptional interest, inasmuch as it contains about six and a half per cent. of the extremely rare element germanium, is described by Prof. Penfield, of the Sheffield Scientific School, U.S., in the August number of the *American Journal of Science*. Germanium was discovered in the year 1886 by Prof. Winkler in the Freiberg mineral *argyrodite*, a double sulphide of silver and germanium. The remarkable manner in which the new element was found to correspond with the *ekasilicon* predicted by Prof. Mendeleëff will be still fresh in the minds of chemists. Germanium thus belongs to the fourth or tetravalent vertical group of the periodic classification, occupying the space previously vacant between silicon and tin vertically and gallium and arsenic horizontally. Its atomic weight of 72·3 corresponds almost exactly with the number assigned to the missing *ekasilicon* by Prof. Mendeleëff. The occurrence of this interesting element appears, as far as the writer can gather, to have been noticed previously in only one other mineral specimen besides *argyrodite*, namely, in *euxenite* by Prof. Krüss, two years after its discovery in the former mineral. Since that time Prof. Winkler has prepared a large number of its compounds and from time to time described their properties, so that we now possess a considerable amount of information concerning germanium. The third mineral now announced was brought from Bolivia by Mr. Canfield as a new, rich, and very beautiful silver ore, and submitted to Prof. Penfield for examination. It has been termed *canfieldite* in honour of its finder. The presence of germanium was suspected from its behaviour when heated in closed and open tubes and on charcoal, inasmuch as it much resembled the behaviour of *argyrodite* under similar circumstances. Perhaps the most remarkable characteristic of germanium is that it forms a *white* sulphide, GeS_2. On heating *canfieldite* in a closed tube the sublimate of sulphide was observed to be white, and, moreover, when the mineral is heated on charcoal a white sublimate of oxide and sulphide is produced near the residual bead of metallic silver, together with a number of milk-white semi-transparent fused globules characteristic of germanic oxide, GeO_2. Eventually most of the compounds of germanium were prepared from the mineral and their properties found to correspond in all respects with those described by Prof. Winkler. A sulphosalt soluble in solutions of caustic alkalies like the sulphosalts of tin, antimony, and arsenic was obtained, and the alkaline solution yielded a precipitate of the white sulphide upon the addition of a dilute acid. When this sulphide, GeS_2, was heated in a current of hydrogen, small glittering scales of the lower sulphide, GeS, much resembling crystals of specular iron ore, were formed just beyond the heated portion of the tube; upon continued heating complete reduction occurred, metallic germanium itself being deposited upon the walls of the tube in small greyish-white octahedral crystals which exhibited a particularly brilliant metallic lustre.

Canfieldite, upon analysis, yields numbers which indicate that its composition is Ag_8GeS_6, or $4Ag_2S.GeS_2$. Prof. Penfield points out that the published analysis of Prof. Winkler's for *argyrodite* agrees much better with the same formula than with the formula $3Ag_2S.GeS_2$, which he ascribes to it in his memoir. Prof. Penfield confirms this by another analysis of *argyrodite* conducted with an excellent specimen in his possession. The two minerals would thus appear to possess the same composition. They are not identical, however, for *argyrodite* crystallises in the monoclinic system. *Canfieldite* crystallises in cubic octahedrons modified by dodecahedral faces; the crystals are black with a blue or purple sheen, they exhibit a magnificent metallic lustre and are extremely brittle. *Argyrodite* and *canfieldite* are therefore dimorphous forms of silver germanium sulphide.

NOTES from the Marine Biological Station, Plymouth.—Last week's captures include the Hydroid *Myriothela phrygia*, the semi-parasitic Rhabdocœle *Fecampia erythrocephala*, and the Mollusca *Favorinus albus* and *Rostanga coccinea*. The floating fauna has changed very slightly since last week, but several other autumn forms have made their appearance. Radiolaria have been present in fair numbers; the Anthomedusa *Podocoryne* (= *Dysmorphosa*) *carnea* has been plentiful, the majority possessing buds upon the manubrium; and the beautiful larvæ of the Prosobranch *Rissoa* and of the Opisthobranch *Ægirus punctilucens* have also been taken. The Turbellaria *Fecampia erythrocephala* and *Cycloporus papillosus*, and the Crustacean *Hyas coarctatus* are now breeding.

THE additions to the Zoological Society's Gardens during the past week include two Ruffed Lemurs (*Lemur varius*, ♂ ♀) from Madagascar, presented by Mrs. Brightwen; three Long-eared Owls (*Asio otus*) and one Tawny Owl (*Syrnium aluco*) from Europe, presented by Mr. Edmund Hart, F.Z.S.; a —— Falcon (*Falco* ——) from ——, presented by Lord Lilford, F.Z.S.; five shags (*Phalacrocorax graculus*) from Scotland, presented by the Maclaine of Lochbuie; a Common Chameleon (*Chamæleon vulgaris*) from North Africa, presented by Mr. E. Palmer; a Black-headed Caique (*Caica melanocephala*) from Demerara, deposited; a Regent Bird (*Sericulus melinus*) from Australia, purchased.

OUR ASTRONOMICAL COLUMN.

THE ORIGIN OF NEW STARS.—Prof. A. W. Bickerton writes to us from Christchurch, New Zealand, as follows:—"More than a year has elapsed since the first notice appeared of the new star in Aurigæ, and up to date no generally-accepted explanation of the special phenomena noted has been offered in any of the leading journals. May I beg to draw the attention of your readers to several articles bearing directly upon the mode of origin of new stars, published fifteen years ago in the Transactions of the N.Z. Institute? The explanation there offered appears to fit in almost exactly with the actual conditions as observed in this particular case. The papers referred to are contained in vols. 11, 12, and 13 of the Transactions of the N.Z. Institute. A summary of these papers also appears in the Proceedings of the Australasian Association for the Advancement of Science for the year 1891." Upon referring to the above references we find that Prof. Bickerton believes that new stars are caused by the "grazing" collision of stars like the sun. His researches show that "The temperature developed is independent of the amount of grazing. With similar substances it depends only on the velocity destroyed, so that the coalesced body produced by the merest graze must be as hot as though the whole sun collided. The molecular velocity of such a high temperature may be sufficient to carry away every particle entirely into space, the mass of the body not having sufficient attractive power to retain them. Hence an intensely brilliant body is produced in less than an hour; it then expands and increases in size and total luminosity for perhaps a few hours to a day or so; then the diffusion would be so great as to gradually lessen luminosity, until in a few months or a year the star would have disappeared into space. This represents all the peculiarities of temporary stars. If the graze be more considerable the attraction will be greater, yet the molecular velocity is the same: a hollow globe of gas may then result, giving us a planetary nebula. According to Lord Lindsay this is the condition of the temporary star in the Swan."

THE SPECTRUM OF THE RORDAME-QUÉNISSET COMET.—Prof. Campbell in *Astronomische Nachrichten*, No. 3177, gives a detailed account of the visual and photographic observations that he has made of the spectrum of this comet at the Lick Observatory. The following are the visual observations, and in the fourth column are given Kayser and Runge's wave-lengths for the edges of carbon bands.

July 11.	July 12.	July 17.	Carbon bands.	Description of bright lines and bands.
600	601	—	619·595	Maximum of red band, broad, faint.
562	—	—	563	Red edge of yellow band.
—	—	5633	5635	Very faint line terminating in yellow band.
—	—	558	5585	Bright line in yellow band.
5162·1	5161·8	5163·9	5165·2	Very bright line terminating in green band.
5124	5127	5128	5129	Very bright line terminating in green band.
—	—	509	—	Very bright line terminating in green band.
4734	—	—	4737	Red edge of blue band.
—	—	4734	4737	Bright line terminating blue band.
—	434	—	—	Bright region in continuous spectrum, faint.
—	421	—	—	Bright region in continuous spectrum, faint.

In addition Prof. Campbell has obtained two photographs of the comet-spectrum extending from wave-length 487 to 387. Twenty-eight bright lines have had their positions determined in the photographic spectrum, fourteen of which appear to correspond to lines and bands of carbon and cyanogen as given by Kayser and Runge. It is pointed out, however, that the wave-lengths of the comet-lines are systematically less than Kayser and Runge's by one or two tenth-metres. Prof. Campbell thinks this may in part be due to the fact that the cometary spectrum consists of unsymmetrical bands rather than lines, and partly to motion in the line of sight.

ATMOSPHERIC REFRACTION AND STAR PHOTOGRAPHS.—Now that stellar parallax is determined from photographic data, and a catalogue of stars is being prepared from the images impressed by celestial points upon sensitive films, it becomes necessary to investigate the effect of each and every cause tending to vitiate the results. Prof. A. A. Rambaut considers the most important of these disturbing causes in a paper on the distortion of photographic star images due to refraction read before the Royal Dublin Society on April 19, and just published in a separate form. Prof. Rambaut had previously published formulæ (*Astr. Nach.* 3125), by which the correction for refraction to the relative position of any two stars on a photographic plate can be computed in a convenient manner, and he has now followed these up by determining the distortion that takes place in the shape of a star-image during the exposure. His conclusion is that within the limits of an exposure of fifteen minutes' duration, "so long as the zenith distance does not exceed 60° no sensible error can arise through the distortion of a star by refraction if the measures are in all cases made from the centre of the image, and the coefficients in the formulæ of reduction are computed for the time corresponding to the middle of the exposure, but if photographs obtained with longer exposures are utilised for the determination of the relative position of stars, it will be necessary to know what star on the plate was used as guider, and the distortion by refraction must be investigated for all stars at any considerable distance from it." From this it will be seen that the photographs of stars obtained for the determination of parallax, or in connection with the star catalogue, are unaffected by the result, since the exposure in each case is usually less than the limit defined by Prof. Rambaut.

ASTRONOMY POPULARISED.—We have previously referred to a proposal to issue a new astronomical periodical, designed for amateurs, teachers, students of astronomy, and the public generally. The first number of this *Popular Astronomy* will be published about September 1, by Mr. W. W. Payne, Goodsell Observatory, Carleton College, Northfield, Minn., U.S. Messrs. William Wesley and Son, 28 Essex Street, Strand, London, are the agents for England. The periodical will be issued monthly, but no numbers will be published for July and August of each year. One of the features will be a scheme of work suitable for a small telescope, field glass, opera glass, and the naked eye. Those who wish to know their way about the sky will find their wants supplied, and home readers will be catered for by means of lists of best books and schemes of study. From these and other matters mentioned in the prospectus it seems probable that the periodical will possess the features that command success.

COMET APPEARANCES IN THE YEAR 1892.—Prof. H. Kreutz has collected together all the appearances of comets during the past year, this list appearing in the *Vierteljahrschrift der Astronomischen Gesellschaft*, 28 jahrgang, parts 1 and 2. In addition to short descriptions of the appearances put on by them at the times of discovery, and to the values of the elements of the new ones, he gives references to all the observations that have been made of them. Among those that receive more than usual attention are Comet 1892 I., discovered by Swift; Comet Holmes (1892 III.), Winneike's Comet (1892 IV.), and Comet 1892 V. (Barnard), since it was the first (excluding that photographed in the Solar Eclipse of May 17, 1882) discovered by photography.

GEOGRAPHICAL NOTES.

THE Society for the study of French Congo has organised a strongly-manned expedition to survey the valley of the Kuilu and Niadi rivers, in order to ascertain the feasibility of constructing a railway from the coast town of Loango to Brazzaville on Stanley Pool. A geological and botanical staff accompany the survey party, and the whole is under the command of M. A. Le Châtelier, who, with fifteen French members of the expedition, sailed from Marseilles last week.

RUSSIAN authorities are determined this year to test the capabilities of the Kara Sea route to Northern Siberia. A small fleet of three vessels, specially built on the Clyde for navigation on the Upper Yenesei, has recently set out in charge of Russian naval officers, who are confident of making a rapid journey. Capt. Wiggins is also in charge of some vessels laden with railway material for the great trans-Siberian line, which are now on their way to the Kara Sea. Dr. Nansen, in the *Fram*, must now be very near the entrance to the Kara Sea, and the nature of the ice there will determine which of the three routes into the sea will be attempted. The ultimate establishment of a commercial steamer service is only a matter of money.

IN a racy little pamphlet, *La Géographies dans les Chaires de l'Université*, Dr. Maurice Viguier makes a raid on a number of elementary text-books published by the leading geographical professors of Paris, and he succeeds in showing many errors of statement which should be set right. He goes on to argue that the inaccuracy of these popular schoolbooks, written to satisfy an arbitrary syllabus, proves the geographical incompetence of the authors. Few eminent men in any country could stand such a test, and in truth the faults cited and held up to ridicule so cleverly are faults of composition rather than of fact, and the worst are due to the ambiguity of words in common speech.

PRELIMINARY arrangements are being made for the meeting of the Sixth International Geographical Congress in London in 1895. This congress will be under the patronage of the Queen, and will bring together the geographers from all countries for the discussion of questions in which the international or universal side of geography will be kept to the front. The month of the proposed meeting has not yet been fixed.

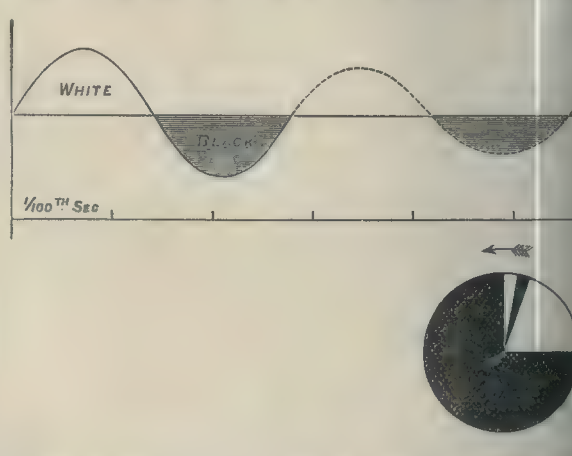
THE Central African telegraph line, projected by Mr. Cecil Rhodes, has been already commenced, and contracts have been signed for its construction from Fort Salisbury as far as Lake Nyasa. The wire will be carried on iron poles, and taken across the Zambesi (a distance of about half a mile) overhead at a height sufficient to allow the traffic on the river to pass entirely unimpeded. The advantage of this line in bringing the region of the great lakes into telegraphic touch with Europe will be very great.

CHARPENTIER'S EXPERIMENTS DEMONSTRATIVE OF AN OSCILLATORY PROCESS IN THE ORGAN OF VISION AND OF ITS DIMENSIONS.

ONE of the fundamental positions in Hering's physiological theory of visual sensation is that each sensificatory datum diffuses in the retino-cerebral organ beyond its precise locus of incidence, and thus directly modifies contiguous sensificatory data. A very elegant experimental substantiation of this position is contained in two simple optical observations by Charpentier[1] (of Nancy) giving not only the clearest possible demonstration of the fact itself, but an approximate measure of the physiological duration and velocity of the phenomenon.

These experiments are (1) that of the "black sector," demonstrative of a retino-cerebral oscillation; (2) that of the "fluted band," demonstrative of the propagation of that oscillation.

(1) *Charpentier's experiment of the Black Sector.*—A black disc with a white quadrant, revolving once in two seconds, illuminated by a very bright light (preferably direct sunlight). Observer's eye fixed upon centre of disc. A narrow black sector appears on the white quadrant near the receding edge of the black surface. This is interpretable as a rebound effect indicative of an oscillatory process in the retino-cerebral organ; the first effect at the arrival of the white border is the sensation of white, and this first effect is followed by an after-effect that is black. On closer examination it may be noticed that the angular breadth of the black sector is equal to the breadth of the white



interval between it and the receding black border, and that these breadths increase and diminish with increase and diminution in the speed of revolution; estimating from this speed and from the apparent extent and position of the black band, Charpentier finds that the white phase and the black phase have each a duration of ·014 to ·016 second, *i.e.* that a total oscillation of the two phases lasts ·028 to ·032 second, *i.e.* that the oscillation frequency is 36 to 31 per second.

Nothing can be clearer and more striking than this experiment; provided a strong light is used, it can be roughly demonstrated without any elaborate apparatus; it can be done by a black and white disc slowly turned round by hand, or by a

[1] *Comptes Rendus*, Soc. Biol., Mai 16, 23, 30, 1891. *Comptes Rendus*, Acad. Sc., Juillet 27, 1891. *Arch. de Physiol.*, Juillet et Octobre, 1892.

black and white card moved horizontally in front of the eyes. The estimates that I have made with proper apparatus very closely correspond with the value as originally determined by Charpentier. With a disc revolving once in two seconds, I find the apparent angular magnitudes of the two phases equal to about $2^\circ \cdot 5$; with a disc revolving twice as fast they are about 5°.

(2) *Charpentier's experiment of the Fluted Band* is somewhat more difficult of performance and of interpretation. A black disc, 45 cm. in diameter, revolving about twice per second, with a small white spot (1 cm. × ·5), 20 cm. from the centre. Observer's eye fixed upon a bead placed in front of the disc at that distance from the centre. Under these circumstances the white spot appears stretched out to a white band with indefinite beginning and end, which appears to be composed of several alternately lighter and darker portions of longer light internodes with shorter dark nodes. Whereas in the experiment of the black sector, the apparent angular magnitude *increases* with increased speed of revolution, in this experiment the angular magnitudes of the nodes and internodes *diminishes* with increased speed (or what amounts to the same thing, with approximation of the observer's eye to the disc) and *vice-versâ*.

Charpentier explains this at first sight very puzzling relation by the following hypothesis, which is at the same time an ingenious application of a well-known physical principle to a hypothetical physiological wave transmission *and a proof of the existence of the latter*. Upon the incidence of the stimulus white, an oscillation of sensation is produced, of which the first or positive phase is white, the second or negative phase black; each phase has a duration of about 0·015 sec.—*i.e.* the entire oscillation has a duration $t = 0{\cdot}03$ sec. and a frequency n of 33 per sec. This much is demonstrated by the experiment of the black sector. Let us now suppose that the oscillation spreads from its origin in the organ of vision[1] over the remainder of that organ, as an oscillation at one point of a pond spreads over the remainder of the pond. The problem is to determine the velocity of transmission v and the wave-length l of this presumably *propagated* oscillation. This is done by Charpentier by the following physiological application of Döppler's principle *re* the apparent modification of sound-waves according as the distance between origin and ear is increasing or diminishing.

In accordance with a familiar relation, wave-length l is equal to velocity v, multiplied by duration t, or $l = vt$. In accordance with Döppler's principle the apparent rise of tone or the apparent diminution of wave-length caused by the approximation of observer and wave origin, are such that $l' = (v - v')t$, where l' is the apparent wave-length, and v' the velocity of approximation.

If we were debarred from measuring tones proceeding from stationary origins, we might nevertheless determine their wave-length and velocity by calculation from measurements of the apparent wave-lengths of tones proceeding from origins moving at different known velocities. From two equations, $l' = (v - v')t$, $l'' = (v - v'')t$, we should have $t = \frac{l' - l''}{v'' - v'}$ and its reciprocal, $n = \frac{v'' - v'}{l' - l''}$ and (substituting $\frac{l}{v}$ for t) $v = \frac{l'v'' - l''v'}{l' - l''}$ and $l = \frac{l'v'' - l''v'}{v'' - v'}$.

These are, in fact, the data experimentally accessible in the retinal phenomenon. We cannot (as far as is known at present) measure the velocity and length of a retinal wave with stationary origin; we must determine these values from their apparent values with the wave-origin moving at different known velocities.

Practically the velocities v', v'', &c., of the wave origin on the retina are easily adjusted; the apparent wave-lengths l', l'', &c., more or less accurately observed. Given the dimensions of the disc, its distance from the eye and its rate of revolution, the experimental velocities are easily calculated; similarly if the apparent dimensions on the disc of the nodes and internodes are accurately observed, the retinal wave-lengths corresponding with them can be accurately calculated. It is in this second determination that the chief experimental error can arise; nevertheless, considering the original conditions of the problem and and that this is, in fact, the first time it has been approached and solved by any method, the results given by Charpentier are, within limits, sufficiently demonstrative of the propagation of a retinal oscillation and of its approximate velocity and wave-length. He finds from a large number of measurements a *velocity* between the limits of 53·8 and 90 mm. per sec. (mean value, 72); a frequency between 28 and 54 (mean value, 36); a calculated wave-length on the retina of 2 mm.; and a calculated wave-duration of 0·028 sec.

[1] It is essentially indifferent whether we take organ of vision to signify the retina or brain or retino-cerebral apparatus. It is convenient to refer measurements to the retina itself, and to determine retinal velocity and retinal wave-length.

Not the least satisfactory feature of these figures is that the value of the wave-duration derived by the indirect method of this more difficult experiment, practically coincides with that derived from the simple and easy experiment of the black sector.

A third experiment of Charpentier's, although not precisely confirmatory of these, seems to stand in some relation to the negative semi-vibration manifested as the black sector. A black disc with open sectors, revolving between the eye and a white sheet illuminated by direct sunlight, gives rise to the sensation of a magnificent purple colour, when the rate of revolution is such that the eye receives between 40 and 60 stimuli per second, *i.e.* when each stimulus occurs during the negative phase of the preceding stimulus. Above 70 and below 30 stimuli per second the sheet appears white. The effect is very striking and very easily obtained; in short, it is a "ladies' experiment"; its full explanation is a different matter, and far too uncertain for discussion in a short article.

A. D. W.

THE POSITION OF SCIENTIFIC EXPERTS.

FROM time to time it has been pointed out in these columns that the services rendered to litigators as such by so-called scientific experts is antagonistic to the pure spirit that should actuate men of science. For some years the position and character of the representative of science in courts of justice has been acquiring interest, not only in England but elsewhere. In fact, a few years ago a Committee of the American Association for the Advancement of Science was appointed to consider the whole matter, but no report of their proceedings has yet been published. An excellent discussion of the subject, however, comes from America in the form of a reprinted lecture on "The Scientific Expert in Foreign Procedure," by Prof. C. F. Himes, which appears in the June number of the *Journal of the Franklin Institute*. In order to direct the discussion, Prof. Himes first gives legal opinions as to the status of the expert. "Justice Miller," he says, "exhibited a plan of objection in a charge as follows:—'My own experience, both in local courts and in the Supreme Court of the United States is, that when the matter in contest involves an immense sum in value, there is no difficulty in introducing any amount of expert testimony on either side.' Another judge, in a lecture upon medical expertism, gives a similar opinion, that the ground of dissatisfaction in regard to medical testimony to both the professions of law and medicine, are reducible to one—that upon every conceivable issue expert opinions are procurable which sustain, or seem to sustain, the most contradictory views." But Prof. Himes does not take a pessimistic view of the scientific expert. He is inclined to believe that:—

"The scientific expert is simply a product, and an extreme product, of an advanced and rapidly advancing civilisation. He was recognised in the germ, to be sure, by the old Roman law, and we may assume in all systems of jurisprudence; but he has acquired an immensely increased importance, and a much wider field and a far greater frequency of employment by the recent, and very recent, marvellous advances in the applications of science—applications which have increased the sphere of things to be litigated about, which have introduced facts of an entirely new character to be adjudicated upon, to say nothing of the contribution that science has made, and is continually making, in many ordinary cases, of conclusive missing links of evidence which render decision previously uncertain, comfortably certain, and satisfactory.

"Now, one fact that seems latent in these expressions of the legal profession in regard to the scientific expert, and almost the first that impresses is that in many respects he seems to be a positive annoyance to lawyers, and even to judges at times—a sort of intractable, incompatible, inharmonious factor, disturbing the otherwise smooth current of legal procedure; too important or necessary to be ruled out, too intelligent and disciplined mentally to yield without reason to ordinary rules and regulations of the court, with which he may not be familiar, and, at the same time, possessing an undoubted influence with a jury, that it is difficult to restrict by the established rules and maxims of legal procedure."

After a consideration of the circumstances that shape the reputation of the scientific expert with the bar, bench, and laity we read :—"In considering some of the sources of dissatisfaction with the scientific experts, perhaps one of the first to suggest itself, and one of the most prolific, is the vagueness of the legal definition of the term 'scientific expert' before alluded to, but which on more careful consideration might rather be termed vagueness and variableness of the standard. Definitions of things are of ideals, and consequently definition is followed closely by the statement that the thing defined is non-existent. The ideal circle is defined, so the ideal solid, the ideal liquid; these definitions are only approached, never realised. Degrees of approach constitute the differences. Practically the courts are limited to the best experts extant in any field, though they may at times fall far short of the ideal. But it is to be feared that in many cases the experts fall below a reasonable and possible standard, and far below the standard that would be fixed by scientific men themselves, as well as below the exigencies of the case. This may easily be accounted for. A party presents a witness as an expert. The judge must pass upon his competency upon such examination as he can make. That decision, though not necessarily, nor even by unvarying practice, a matter of discretion, will not often be reviewed by a superior court. Often, then, the best solution, certainly the easiest, seems to be to admit, even where there may be grave doubt as to qualification, and to throw the burden upon the jury, already overburdened with questions, which the theory of trial by jury assigns them, questions which they are not qualified to deal with, although they may be fully up to the average in general intelligence. At a time when experts were not much beyond men in the ordinary avocations of life it may have been reasonable to require the jury to pass upon the 'weight and credit to be given to evidence viewed in connection with all the circumstances,' but under the changed circumstances of to-day, with experts of a character, and upon questions not dreamed of even a century ago, it seems to be straining a theory too far to put upon an average jury the decision of so grave a question, as to the character of the expert, which the court may not be able to settle satisfactorily. But for the theory it would not be thought of, if a system of jurisprudence were now being devised. Now among the results incidental to a liberal interpretation of the term by the courts are many that are regarded as the gravest evils of expert testimony. With doors wide open to incompetent persons, very slight pecuniary advantage, and still more frequently the incidental benefit attributed to notoriety and advertisement would cause them to seek entrance. As a result differences of opinion may be anticipated where knowledge is wanting as a basis. Then, too, the number of such experts in any case will be greater. The cross-examination absolutely necessary to test such evidence must be exhaustive and tedious. Trials are prolonged. The expense of the administration of justice is increased without furthering its ends, and withal often with incidental discredit not only of the testimony of experts, but in a measure of the whole judicial procedure which is responsible for them; and the jury are often left in such a state of mental confusion that the evidence can only be weighed by counting the experts. Now the rule should tend toward a greater strictness in regard to the qualifications of experts, since the progress of science tends towards a greater degree of specialisation in study, and consequently to more minute and extended evidence on the whole, with greater restrictions on the range of best evidence of any particular expert. If science stood still, or if forensic science was confined at all times to the same old ground, everything would be settled, but as it is, the new points at issue continually arising make new demands upon experts, which there may be few at first qualified to meet. The introduction of advanced scientific expert testimony is then hardly a matter of option. It is forced upon the courts by the fact that science is just as ready in the hands of the unscrupulous and dishonest to perpetrate the most flagrant wrongs as to aid in their detection, and that there is no advance in science that is not as accessible to the enemies of society as well as to society itself.

"But another, even more prolific source of complaint than laxity of rule in the admission of experts, lies in the anomalous position of the expert in many respects, and under the best circumstances. He is legally a witness, an ordinary witness, but practically with extraordinary functions and one loaded with extraordinary responsibilities, and one might add, frequently loaded with extraordinary, and even absurd, expectations. As a witness he is subpœnaed by the same form, obliged to respond under the same penalties, to take the same oath; is subject to the same rules and restrictions, and the same treatment in court. He has no higher claim upon the State, or upon the parties for his time or his private professional knowledge, which constitutes his livelihood. He receives, in most cases, to be sure, from the party calling him, a fee agreed upon between them, and certainly out of proportion to those of other witnesses, even if it is not professional in magnitude. He assists the side on which he is called in working up its case. He suggests the cross-examination of witnesses. He thus exhibits the character of a very willing witness, of a well-paid witness, combined with a great deal of the advocate. Now he cannot be held responsible for this position, but the system of jurisprudence, which not simply permits it, which has not simply taken him, but has forced him in, and which, apparently cognizant of all, seems only able to originate complaints, rather than to provide a different character for him; for there seems, indeed, in many of the adverse criticisms of experts, to be only a confession of weakness, rather than a disposition earnestly to consider the whole question with a view to the radical remedy of the evils. The human nature of the judge is recognised and provided against. Every safeguard is thrown around him to protect him from bias, or possible suspicion of bias, which would be almost as bad. The jury is selected so as to be free from bias, and is protected as well. Other witnesses are not expected to take the part the scientific expert is almost compelled to take. In fact, if deliberately planned, there could hardly be a network of conditions devised, calculated to produce so many of the evils of scientific expert testimony complained of, or to cloud this testimony of highest intrinsic value, having the highest degree of certainty, and in a field altogether its own."

"But in regard to the charge of bias," Prof. Himes afterwards goes on to say, "it may be admitted that the scientific expert may at times be biased, but that is only admitting that he is made of the same clay as other men. The bias, if not produced by the call, would certainly not be more of a reflection on his character than upon the system of jurisprudence which renders a call based upon bias not only possible, but almost necessary, and which provides no other method for the introduction of scientific testimony. But bias may be in nowise incidental to the call. It may be a purely scientific bias, due to some peculiar view or theory. No kind of training will fortify a man against bias at all points. In his laboratory, in conducting his investigations, the scientific expert may keep himself free from bias. The judge upon the bench is free from bias by habit, rather than by conscious effort. But even the judge, placed in some novel position of great responsibility, which this judicial habit does not fit exactly might lapse into a bias. . . .

"The criticism due to differences of opinion frequently exhibited by scientific experts can hardly be regarded as a serious matter by a profession characterised by differences of opinions on all conceivable points; the only settled opinions known to it being those of the court of last resort, which even claims the privilege occasionally of reversing itself. Differences of opinion among scientific experts are often doubtless due to differences in scientific character, resulting from the loose rule of admission. But there may still be honest differences between experts of highest character. I think such, however, it will be found, are rarely in regard to well-established facts, but oftener in regard to probable inferences from facts, whilst entire agreement would be marvellous in matters of theory and speculation. Courts and attorneys do not discriminate sufficiently between well-established scientific facts and scientific theories. Some of the most recent and far-reaching decisions of our highest tribunals have a basis of theory rather than of fact."

This leads to a point which we have always insisted upon, namely, that a scientific expert should not be called and subsidised by a particular side, but should be appointed by the judge or jury. To quote Prof. Himes :—

"Many of the most objectionable features of the expert witness originate in the mode of his entrance into court, and it is an allowable question, whether any modification could be made in the calling of the witness. Among the reports one judge expresses the opinion that, 'expert witnesses ought to be selected by the court, and should be impartial as well as learned and skilful. A contrary practice, however, is now probably too well established to allow the more salutary rule to be enforced.' Another judge suggests that the law should be so changed 'that this class of witnesses should be selected by the court, and that this should be done wholly independent of any nomination, recommendation, or interference of the parties, as much so to all intents as are the jurors.' This would not make experts *amici curiæ* any more than before, for all witnesses should be regarded in that light, but it would be a provision rather to preserve that character to them, coupled as it is with a recommendation as to compensation, so intimately connected with it. It is not the fact of extra compensation, or that the compensation is paid by the party benefited by his testimony, that creates the unfavourable impression. The other witnesses are friends of the court, by whatever party they may be called, they stand upon the same footing as to pay; but here is a witness who is paid according to a private agreement, by one of the parties; the amount is their own private arrangement on which the court is not consulted, over which the court has no control, a circumstance that imparts to him, in high degree, the character of a friend of one of the parties; and these facts as to compensation are often elicited at a time, and in a way, calculated to impair otherwise valuable testimony in the minds of the jury.

"By far the best plan seems to be that adopted in the Imperial Courts of Germany. For certain matters and lines of business permanent experts are appointed by the State, but they are not regarded as officers, but as *employés* for the time being. They have no official title, nor regular salary. The payment they receive is not enough to support them, but barely compensates them for their loss of time. For most cases the expert is appointed by the particular judge in the case, often on the demand of one or the other or both parties, but the choice of the expert lies within the discretion of the judge. He may appoint any man whom both parties suggested, or may also appoint a third man not suggested by either, but if both parties unite on one man he must listen to his testimony. If a question is involved for which regular legal experts are provided, these need only be or can be appointed. The qualifications for such a regular expert are that he should follow that particular profession or line of business habitually, and for the purpose of earning his living. The number of experts in a case is not limited by law, it rests with the discretion of the judge. The status of the expert in court is almost analogous to other witnesses, but it is not a civic duty, as with witnesses, to give evidence in court except where a profession is followed publicly and for a livelihood. The text of his oath before giving testimony is different from that of an ordinary witness; and he need not be sworn at all if both parties unite in dispensing with such qualification."

If a similar system were followed in England the testimony of scientific experts would be regarded with a little less suspicion than it is at present. Only by some such means can technical evidence of a wholly disinterested character be obtained.

SCIENCE CLASSES IN CONNECTION WITH THE LONDON COUNTY COUNCIL.

THE Technical Education Board of the London County Council has issued a series of Regulations with regard to the administration of grants to science classes. All the prescribed conditions tend to make the instruction efficient and develop technical education in the right direction. The following are those that refer to the manner in which various classes must be conducted:—

(1) That as a condition of aid being granted by the Board for the teaching of chemistry, physics, mechanics, and botany, it will be regarded as indispensable that provision should be made, to the satisfaction of the Board, not only for the experimental illustration of the lectures or class teaching, but for experimental work by the students themselves, either in laboratories belonging to the institution or, where this cannot be arranged, in the laboratories of some neighbouring institution with which the class should be associated; and every lecture must be followed by at least one hour's practical work on the same evening, or some other evening in the same week.

(2) That with regard to classes in the subjects comprised in the Science and Art Department Directory which are more strictly to be included under the head of technology, viz. building construction and drawing, machine construction and drawing, steam and the steam-engine, navigation and naval architecture, it be required, as a rule, that such classes be taught by teachers having a practical acquaintance with the industries to which they refer; provided that, in the case of teachers who have already successfully taught such classes, it shall be open to the Board, on being satisfied of the sufficiency of the qualifications, to make exceptions in particular cases. No grant will be given for classes in agriculture or mining.

(3) That for classes in geology and mineralogy suitable museum specimens be provided and examined by the pupils, and for classes in machine drawing a suitable collection of models and parts of actual machines be provided.

(4) That in the teaching of mathematics, practical geometry, building construction, machine drawing, naval architecture, navigation and nautical astronomy, "home work" be made an important feature, and that the students' work be examined and corrected by the teacher out of class hours.

(5) That in all practical laboratory classes, and in classes on mathematics, practical geometry, building construction, machine drawing, naval architecture, navigation and nautical astronomy, not more than twenty students shall be under the charge of one teacher at the same time, but where more than one teacher is present during the whole meeting of the class the number of students may be increased in proportion to the number of teachers.

(6) That in all subjects there be a sufficient supply of apparatus and materials for efficient teaching, and that such apparatus and materials be effectively used.

(7) That no payment be made on account of pupils who, in the opinion of the Board, may not reasonably be expected to profit by the teaching provided (*e.g.* pupils in navigation or nautical astronomy, or in the advanced stage of theoretical or applied mechanics who have insufficient knowledge of mathematics; those in building construction or machine drawing who have no knowledge of elementary mechanics, &c.).

The Board is prepared to consider applications for assistance to erect laboratories and provide the necessary equipment. It will also make grants in aid of the purchase of apparatus for science teaching. With so many advantages, technical education in the administrative county of London should grow apace.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE following is the list of candidates successful in the competition for the Whitworth Scholarships and Exhibitions, 1893:—Scholarships (tenable for three years, having an annual value of £125):—William Hamilton (Glasgow), John G. Longbottom (Keighley), Arthur E. Malpas (London), Richard J. Durley (London); Exhibitions (tenable for one year, having a value of £50):—Charles F. Smith (Glasgow), John Ball (Derby), William Buchan (Glasgow), John B. Chambers (London), Henry J. Loveridge (Southsea, Portsmouth), William F. Ireland (Glasgow), George W. Fearnley (Shipley), Oliver Styles (Edinburgh), George M. Russell (Portsmouth), Alexander A. Jude (Hull), Edward R. Amor (Devonport), Joseph Jeffery (Birmingham), Paul J. Reynolds (Plumstead, Kent), Thomas Pilkington (London), Richard Reynolds (Cardiff), George Wilson (Sheffield), Walter O. Hammant (Plumstead, Kent), John Orr (Airdrie), William I. Chubb (London), Henry Smith (Brighton), Frederick D. Green (Wanstead, Essex), John Powell (Crewe), James H. Hardy (Woodley, near Stockport), James H. Shepherd (Swindon), Herbert Thompson (Sheffield), Evan Stevens (Swindon), Henry E. Morrall (Wolverton), Herbert Bates (Manchester), Charles H. Hill (Stratford, London), William F. Massey (Newport, Salop).

The Scholarships Committee of the 1851 Exhibition Science Scholarships has issued a list of appointments for 1893. Four scholarships awarded in 1891 have been renewed for a third year in order to permit the holders to complete their investigations. These scholars are James H. Gray, John Joseph Sudborough, Harry Ingle, and Thomas Ewan. The following scholars of 1892 have had their scholarships renewed for a second year:—Andrew John Herbertson, James Blacklock Henderson, John Macdonald, Lionel Simeon Marks, George Lester Thomas, Harold Hart Mann, James Terence Conroy, Thornton Charles Lamb, Edward Arnold Medley, William Henry Oates, William Gannon, Frederick J. Smale, Samuel Henry Barraclough, David Hamilton Jackson, Edward Taylor Jones, James Bernard Allen. The list of science scholars of 1893 is as follows:—Herbert William Bolam, George Edwin Allan, James Wallace Walker, Arthur Lapworth, John Ellis Myers, Arthur Walsh Titherley, Edward Chester Cyril Baly, John Cannell Cain, Ella Mary Bryant, James Darnell Granger, Mary O'Brien, Frederick George Donnan, James Alexander MacPhail, Norman Ross Carmichael, Wm. Henry Ledger, George Wm. Macdonald. The institutions to be invited to nominate science scholars for 1894 are:—the University of Edinburgh, the University of Glasgow, the University of Aberdeen, Mason College, Birmingham, University College, Bristol, Yorkshire College, Leeds, University College, Liverpool, University College, London, Owens College, Manchester, Durham College of Science, Newcastle, University College, Nottingham, Firth College, Sheffield, University College of South Wales, Cardiff, Queen's College, Cork, Queen's College, Galway, the University of Toronto, Dalhousie University, Halifax, Nova Scotia, the University of Adelaide, and the University of New Zealand.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 7.—M. Lœwy in the chair.—On the periodic maxima of spectra, by M. Aymonet.—On the heat spectrum of fluorine, by M. E. Carvallo. A comparison between the results obtained by the author and simultaneously by Messrs. Rubens and Snow, of Berlin. In those portions which are common to all three observers, the agreement is perfect, although the results were arrived at by very different methods.—On the absorption of light by liquid bromine, by M. Charles Camichel. Liquid bromine absorbs luminous rays very energetically, especially the most refrangible ones. Thus, a thickness of bromine of a wave length and a half of D light exerts a considerable absorptive action upon the green ray of thallium, and a layer of six times that thickness absorbs the same radiation to such an extent that measurements become difficult. A drop of bromine was introduced between two pieces of glass constructed for observing Newton's rings. These glasses were mounted in a screw frame resting upon the carriage of a dividing engine, by means of which they could be moved in front of one of the collimators of a Gouy spectrophotometer. The thickness of the layer was measured by observing Newton's rings in monochromatic light. Two luminous pencils proceeded from the same source, one traversing the polarising collimator, the other the bromine glasses and then the ordinary collimator. Two patches were thus produced, which were equalised by the analyser when the bromine glasses were full and empty respectively. It was found that the absorption followed the exponential law between thicknesses of 0·5 and sixty times the principal wave length of sodium.—On the origin of atmospheric oxygen, by Mr. T. L. Phipson. Various plants, such as *Poa*, *Trifolium*, *Antirrhinum*, and *Convolvulus* were placed under glass shades with their roots immersed in water containing free carbonic acid and certain salts, shut off from the light, and their upper portions exposed to a north light in atmospheres of carbonic acid, hydrogen, and nitrogen respectively. It was found that in carbonic acid the plants were able to live for some time, but did not prosper. In hydrogen they fared better, but the gas gradually disappeared, probably combining with the oxygen evolved by the plants. *Convolvulus* throve very well in an atmosphere of nitrogen, especially if mixed with a third part of carbonic acid. After several weeks the composition of the gas began to approach that of our atmosphere, no change of volume having taken place. The bearing of these facts upon the history of the earth's atmosphere may prove important.—Of the isomorphism of anhydrous alums, by M. T. Klobb.—Influence of solar radiation upon plants, by M. G. Landel. Variations of intensity of solar radiation appear always to act in the same sense upon plants, as regards the quantity of flowers and the proportion of red pigment colouring the various parts. These variations differ much according to the species. In some the red pigment is well developed in the shade, whilst others remain perfectly green. The inflorescence in certain species does not seem to be sensibly modified by shade; in others the number of flowers is less.—The young bulbs of the *Dioscoreæ*, by M. C. Queva.

BOOKS AND PAMPHLETS RECEIVED.

BOOKS.—Mathématiques et Mathématiciens; Pensées et Curiosités deux edition: A. Rebière (Paris, Nony).—Solutions of the Exercises in Taylor's Euclid, Books 1 to 4: W. W. Taylor (Cambridge University Press).—A Treatise on the Mathematical Theory of Elasticity, Vol. 2: A. E. H. Love (Cambridge University Press).—A History of the Theory of Elasticity and of the Strength of Materials, Vol. 2, Parts 1 and 2: the late I. Todhunter, edited and completed by K. Pearson (Cambridge University Press).—British Rainfall, 1892: G. J. Symons and H. S. Wallis (Stanford).—Birds in a Village: W. H. Hudson (Chapman and Hall).—Pocket-book of Useful Formulæ and Memoranda for Civil and Mechanical Engineers, 23rd edition Sir G. L. Molesworth and R. B. Molesworth (Spon).—Report of the Fourth Meeting of the Australasian Association, held at Hobart in January, 1892 (Sydney).—Royal University, Ireland, Examination Papers, 1892 (Dublin, Thom).—Griffin's Electrical Engineer's Price Book: H. J. Dowsing (Griffin).—Les Turbines: G. Lavergne (Paris, Gauthier-Villars).—Fourth Report of the Department of Science and Art (Eyre and Spottiswoode).—Electric Lighting and Power Distribution: W. P. Maycock, Parts 2 and 3 (Whittaker).—Geology, an Elementary Hand-book: A. J. Jukes-Browne (Whittaker).—Electricity and Magnetism: S. R. Bottone (Whittaker).

PAMPHLETS.—U.S. Department of Agriculture, Report of the Chief of the Weather Bureau for 1892: M. W. Harrington (Washington).—Catalogue of the Crabs of the Family Maiidæ in the U.S. National Museum: M. J. Rathbun (Washington).—The Planet Venus: E. M. Clerke (Witherby).—Notes on the Trunk Skeleton of a Hybrid Grouse: R. W. Shufeldt.—Report upon the Scott-Moncrieff System for the Bacteriological Purification of Sewage: A. C. Houston (Waterlow).—On the Distortion of Photographic Star Images due to Refraction: Prof. Rambaut (Dublin).—A Preliminary Report on the Aquatic Invertebrate Fauna of the Yellowstone Natural Park, &c., &c.: S. A. Forbes (Washington).—Notes on a Few Fossil Plants from the Fort Union Group of Montana: F. H. Knowlton (Washington).

CONTENTS.

THURSDAY, AUGUST 24, 1893.

WATER AND ICE AS AGENTS OF EARTH SCULPTURE.

Fragments of Earth Lore: Sketches and Addresses, Geological and Geographical. By James Geikie, D.C.L., LL.D., F.R.S., &c., &c. (Edinburgh: John Bartholomew & Co. London: Simpkin Marshall, Hamilton, Kent & Co., Limited, 1893.)

THESE collected papers form a fairly connected work on the origin of the present surface features of the world at large, and of Scotland in particular. The first is a well-put plea for the more intelligent and far-sighted method of teaching geography, and is followed up by four articles on the geographical features of Scotland, which are of a somewhat advanced and special character, and lead directly to the exposition of the author's views on glacial action. That forms the subject matter of the next eight papers, supplemented by a geographical essay in which he discusses some aspects of the question of earth movements, which are obviously closely connected with the theoretical explanations of climatal change. On the whole, perhaps, another form would have been better; for the advice as to the teaching of geography will hardly be necessary for the same readers as those who, with their local field club, are prepared to follow the author through the Western Islands; while those who wish to examine once more the arguments for the special views on the ancient glaciation of the country which he advocates, would have found the information more usefully arranged for them, if worked into a manual. The style of the articles is sufficiently didactic to have readily lent itself to this form.

The book provides for the author an inventory of his own literary properties, and of some others, in which he has a joint claim, owing to his having independently arrived at the same conclusion as other observers. It provides for him also an opportunity of qualifying statements which further investigation has shown to require modification. In which respect the reader is equally benefited, as he would certainly prefer to receive the results of our author's mature judgment on the subject.

We appeal to him as a leader in geographical science, and one who has abundant facility of expression, not to encourage the absorption of too many words out of our current language for use as technical terms. Such names as *chain* and *range* should be simply descriptive of form, that is of actual continuity, or of contiguity with a linear arrangement, regardless of the origin of the features.

Among the most interesting geographical descriptions given is that of the "drowned lands," or areas which have been moulded into their present form by subærial action, and then submerged with all their hills and valleys (pp. 21, 367, and more fully in art. xiv). We shall know more about this as we get more soundings and the study of oceanography advances.

The feature of greatest importance in the study of geology and geography is the *plain of marine denudation*, the level at which the sea arrests the agents of subærial waste, and at which the wind waves carry on the work. This is the datum from which the amount of rock removed by denudation must be measured: this is the index that tells us how long the great forces of elevation and depression balanced one another: this marks the long drawn-out nodes in the undulations of the earth's crust.

Our author might have dwelt longer on this ground, when giving his views as to how the successive portions of the earth were brought within reach of the denuding agents to which he chiefly refers their sculpture.

Most of the papers are controversial, or they are written so as to strengthen those positions on which some disputed theory has been built up, and are so turned as to allow the author frequently to point the moral which he chiefly aims at inculcating.

We feel quite glad of the genial warmth of the volcanic fires which ushered in the Devonian, and are hardly willing to admit the existence of ice at this age in the Cheviot area. Yet there is no reason why the surrounding mountains may not have been high enough to nourish glaciers, but the shape and condition of the stones included in the conglomerates at the base of the red rocks are hardly sufficient to *prove* this, especially when the ghosts of scratches have in other cases been shown to be due to movements in the rock, which caused the included fragments to be crushed against one another.

After a long interval we read in the history of the Cheviots of Scandinavian ice which over-rode everything, and of the successive interglacial periods when that ice receded only to advance again with hardly less intensity, but we do not know how our author explains its apparently smaller eroding power, seeing that it failed to remove even the peat and silt which had accumulated in the interval.

As an example of the kind of evidence which is occasionally admitted in support of the former extension of land ice we may cite his reference of the implement-bearing gravels of East Anglia to the floods discharged at the foot of the melting ice-sheet.

The argument that the gravels are eighty feet above the sources of the *existing* streams after ages of denudation does not go for much where the level of the outburst of springs has varied within the memory of man; while the flint implement-bearing gravels creep up the hills in terraces with abundant material derived from the boulder clay which covers the tops of the hills all round, but never overlaps those gravels. The shells in the gravels are, with few exceptions, of the same species as those now inhabiting the neighbouring streams, and those exceptions belong to more southern forms. There very likely are marine gravels capping some hills, but they are certainly not correctly referred to as those "with ancient flint implements," &c., in East Anglia.

Although he frequently mentions "the now discredited iceberg theory," he does not often refer any of the drifts to their "random and eccentric action," but explains some of the difficulties of the distribution of erratics by the intercrossing of currents within the ice-mass. Whether or not any particular group of boulders or mass of drift was carried by icebergs or not, it is too much to say that there are no reasons for considering icebergs capable of polishing and striating rock surfaces (p. 219). If we allow that glacier-ice charged with stones and mud can erode its base, surely miles of the very same mass of ice, with the same mud and stones, when broken off and driven by wind and current on a shelving shore, must grind and polish the floor on which it is driven.

It is difficult to follow the explanation offered of the pushing up of shells belonging to temperate climates by the great ice sheet, or the wrenching off of large masses of rock underneath the ice, except on the supposition that all this was done during the *first* advance of the ice over the sea bottom, and over a surface irregularly fretted by subærial action. When once the sea-bed had been swept, no more such life would be there till the ice receded; and, when the crags had once been planed down, there could be no more jagged rock for the ice to break off and carry along. Moreover, it does not seem to have been observed that the flints so universally distributed through the marine gravels, such as those of Moel Tryfaen, are rusty gravel flints, and that there is no long interval without them all round the southern and central portions of the British Isles.

The point, however, to which our author seems to attach greatest importance is the occurrence of interglacial periods. He describes successive sheets of boulder clay, each of which is the accumulation of a separate and distinct ice flow. He points out that the fauna and flora found in beds interstratified in these clays are suggestive of alternations of cold and damp conditions with those indicative of a warm and genial climate. In Scotland and Scandinavia the gradual disappearance of the latest ice-sheets was, he says, marked by a partial submergence, but a great submergence he does not believe in, and, after describing the grand series of moraines which stretches across the northern states of America into the British possessions, says that "no one who has traversed the regions I refer to is at all likely to agree with Sir W. Dawson's view that the American mounds, &c., are the shore accumulations of an ice-laden sea."

We regret the somewhat assured manner in which the views of those who differ from our author are dismissed. Sir William Dawson traversed the regions referred to by him (p. 190) and arrived at a different conclusion; and there are some who have not confined themselves so exclusively to the subjects on which our author has made himself a name, who yet do not deserve to be excluded from the list of geologists because they do not agree with him on every point. It would be well also if he would strike out from any future edition all references to "the trained observer" and "the experienced eye," as his readers cannot help recalling many instances where trained observers have differed in interpretation, and where, the position having been shifted, even the experienced eye has seen things differently at different times.

Though our author could not in these essays discuss fully the various points which must be fixed before any theory can be considered as fairly established, he has indicated the lines of reasoning on which he would rely.

His position seems to be that there are known to recur such astronomical combinations as by a general lowering of the snow line would be sufficient to account for glacial conditions with such distribution of land and water as for instance prevail at present; that with unfavourable geographical arrangement no glaciation is possible; that the greater part of the results observed were produced by land ice, icebergs playing quite a subordinate part, and marine currents of any considerable volume and velocity being quite exceptional; that within each period of possible glaciation there were alternations of conditions of greater or less intensity corresponding to established astronomical cycles, and that the evidence of these were to be seen in certain beds intercalated in the drift. He admits, but explains away, the absence of evidence of the regular recurrence of such effects throughout the previous geological ages.

The geographical theory which he principally combats may be briefly summed up thus: There have been through all time terrestrial movements of wider or narrower extent which have carried portions of the earth's surface to depths below the lowest known abyss, and raised portions through distances greater than the highest mountain peak; the depression and elevation of extensive areas or ridges must, with sufficient precipitation, deflect ocean currents and produce such snowfields as would feed the largest glaciers or ice-sheets required in explanation of the drifts, boulders, and accompanying phenomena; there is evidence of movements on a grand scale since the period of great cold and similar movements have been going on up to a quite recent date, and these, if extended over a longer time, would produce all the effects required.

In the course of these addresses our author is frequently led to speculate upon the causes and some of the effects of earth-movements, and we find (*e.g.* pp. 129, 267, 342) such a good case made out every now and then for the geographical theory that we cannot help feeling that the difference between the two schools is not irreconcileable but this is a vast question which cannot be settled till many possibilities have been considered.

The various theories referred to have been built up on such a number of observations and hypothetical explanations that it is impossible to discuss them in one volume of essays, still less in a short review of that volume.

All the more, however, because the subject involves so many matters of controversy, do we welcome the publication of the latest views of one who is so skilled an observer as our author, and so competent to watch the progress of research in regions beyond that which he has especially studied.

WATER BACTERIA.

Diagnostik der Bakterien des Wassers. Von Dr. Alexander Lustig. Zweite sehr vermehrte Auflage. 128 pp. (Jena: Gustav Fischer, 1893.)

THIS is, we believe, the first attempt made to gather together in a compact form the various descriptions of bacteria which from time to time have been isolated from water by different observers. In those cases where the water investigator is concerned only with the number of microbes present in any given water, the task of mere enumeration is such that, however anxious to do so, it is almost impossible to take an intelligent interest in the nature of the microbes present, beyond a superficial glance at their more striking characteristics. But even this is sufficient to indicate what numbers of different kinds of microbes are present in water, whilst on a closer examination the list of varieties is very much more extended. Having regard to their superficial differences, then, Lustig, following the example set by Eisenberg in his "Bakteriologische Diagnostik," has mapped out two classes of microbes—those which liquefy and those which do not liquefy the gelatine—which are again divided up into micrococci and bacilli respectively. The tabulated account appended to each micro-organism includes its microscopic appearance, behaviour in gelatine-plate and tube-cultures, on agar-agar and potatoes, relationship to pathogenic properties, temperature, together with other special tests which have from time to time been employed, as well as the authority for its discovery in water.

In addition to the above classification, those bacteria which are known to be pathogenic to man and animals respectively are separately grouped, whilst those bacilli resembling the typhoid bacillus are brought together for purposes of comparison. The latter should prove a useful assistance in the separate diagnosis of the typhoid bacillus, for as it is by no means specially characteristic either in its macroscopic or microscopic appearances, there are many forms which may readily be mistaken for it on an ordinary water-plate.

We do not quite understand why Lustig has not rendered the cholera spirillum a similar service. There exist many spirilla in water which bear the most striking resemblance to Koch's comma spirillum, but which subsequent searching tests have proved to be distinct. Koch himself only a few weeks ago stated that no less than a dozen different vibrios had been isolated in his laboratory alone, from various waters which he examined last autumn during the cholera epidemic, none of which were the cholera spirillum, whilst other investigators have identified and described spirilla bearing the closest resemblance to the original comma spirillum.

Amongst the organisms pathogenic to man found in water we miss the tetanus bacillus. This organism was detected by Miquel in the rivers Seine snd Marne, and G. Roux states that he found it in large numbers in the sediment of the filter beds belonging to the water-works supplying Lyon with river Rhône water, whilst Lortet alleges that he discovered it in mud obtained from the bottom of the Dead Sea. In a future edition the anthrax bacillus must also be included, since it has recently been detected in the sediment at the bottom of a well, to the water of which an outbreak of anthrax amongst a flock of sheep was traced.

In the preface to the German edition Baumgarten writes: "Grössere Reihen von 'Wasserbakterien' sind schon früher von anderen Forschern (Frankland, Maschek, Adametz, W. Zimmermann, Tils) auf Grund eigener Beobachtungen und Untersuchungen beschrieben worden. Diese sowie *alle sonstigen*, verstreut in der Literatur . . . ist Lustig's Verdienst vereinigt zu haben." It is obvious that in a guide of this kind the list should be as complete as possible, and it is, therefore, surprising to find many important and quite unaccountable omissions. For example, none of the interesting phosphorescent bacilli obtained from sea-water by Forster, Fischer, and Katz are described, neither is any mention made of the organisms isolated by Russell from sea-water.

Amongst other organisms conspicuous by their absence may be mentioned the *bacillus thermophilus* originally found in large numbers in river Seine water by Miquel, the anærobic bacillus, *B. amylozyme* obtained by Perdrix from the same water, the *bacille rouge de Kiel* so carefully studied by Laurent, the "peach-coloured bacterium" of Lankester, whilst Roscoe and Lunt's sewage organisms, and Tataroff's large collection of bacteria isolated from the Dorpat water are entirely overlooked.

The descriptions appended are often provokingly incomplete, and this greatly militates against the value of the book in assisting in the identification of a particular organism, whilst in some cases the details are not always correct.

The book was originally written in Italian, so possibly during the translation into German errors and misprints may have crept in which were not present in the original, but it is none the less troublesome to find wrong references occasionally given, whilst the description of the same organism twice over, which occurs more than once, ought surely to have been guarded against. As an example of this we may mention a bacillus found by Claessen (mis-spelt Claesten) in unfiltered river Spree water, and described on p. 62 as the *Indigoblauer bacillus*, whilst on p. 70 we find it figuring again as bacillus, *Berolinensis indicus!*

In order to bring the descriptions up to a level with those in Eisenberg's "Bakteriologische Diagnostik," even (and as the volume before us deals solely with water-microbes, they might not unreasonably be expected to be fuller) careful revision will be required, and the evident signs of haste which at present characterise its pages conscientiously removed.

Such an array of different water microbes, to each of which is given a "local habitation and a name," might well make the reader say with the "Ancient Mariner," "Water, water, everywhere, Nor any drop to drink;" but it is reassuring to find that out of the 181 varieties found in water, only six are stated by Lustig to be pathogenic to man. P. FRANKLAND.

POPULAR METEOROLOGY.

Katechismus der Meteorologie. Dritte Auflage, gänzlich umgearbeitet. Von Prof. Dr. W. J. Van Bebber. (Leipzig: J. J. Weber, 1893.)

THE object of the author of this little book is to present as briefly and intelligently as possible the fundamental principles of meteorology, in a manner which will enable the public to form for themselves an independent judgment on the meteorological conditions prevalent at the moment, and to make the knowledge so obtained available for the purposes of daily life. The author, who is well and favourably known as a popular writer on meteorology by his *Lehrbuch*, thinks that this eminently practical object can be best effected by placing his information in a catechetical form; a method of conveying instruction which appears to find great favour in Germany. This particular work is already in its third edition, and is the sixtieth of a series which in its entirety probably comprises more than twice that number of works devoted to the culture of science, art, and industry, and all forming part of the "Illustrierte Katechismen." This form, however, is not one that commends itself generally to the writers of English text-books, at least in modern times. It is believed that the fascinating style of the ingenious Miss Mangnall endeared her writings to an earlier generation, but the peculiar form of which she was so admirable an exponent has not found many imitators. But the case seems to be different in Germany, to judge by the number of works and editions in this catechetical series, to which we have referred. The author contends that the form of the work is suitable, and in his recent revision he has preferred to retain it. But if the questions in a slightly altered shape were made to fill the place of marginal notes, and the information were presented in a continuous readable form, it would, to an English eye at least, be preferable to that adopted, which has all the appearance of a collection of conundrums without their interest. But apart from this question of form, there are two reasons why we are inclined to dissent from the judgment of the author. Meteorology has hardly crystallised into that definite shape in which a cut and dry answer can be given to every definite question. The author seems to take some praise to himself that every hypothesis has been most carefully excluded. But this is a very doubtful merit. It has the immediate effect of excluding much that gives a charm and interest to the study, and without a knowledge of which one can hardly be said to be instructed in meteorology. Working hypotheses, recognised as such, have a distinct value, especially in a science where much is, of necessity, tentative and experimental. The other objection which might be urged against the style arises from the fact that, in the present instance at least, it does not lend itself readily to the description of diagrams. Perhaps this explains why the book is not more profusely illustrated. It was doubtless felt that diagrams did not greatly add to the clearness of description.

The contents of the book are generally such as one would expect to meet in an elementary work on meteorology. There are, however, some exceptions, in which the author enters upon subjects which we are apt in this country to include under the wider title of physiography. After dealing with the temperature of the atmosphere, its daily and annual variations, the peculiarities of isotherms, &c., we have an account of barometric records and variations of atmospheric pressure with theories of the wind. Under this heading are treated such subjects as land and sea breezes, local winds, such as monsoons, and movements of the atmosphere affecting small areas. The transition to such subjects as the Gulf Stream and ocean currents is easy if a little unexpected, but the author soon returns to topics more immediately connected with meteorology properly so called. The subject of evaporation, and the deposition of moisture in its various forms, is sufficiently dealt with, and if there is nothing new in this chapter it is clear and satisfactory, and the same can be said for the few concluding questions on electrical and optical phenomena. A few remarks might have been added with advantage on the aurora, but possibly the author was afraid of hypotheses.

The most readable and the most interesting portion of the book is undoubtedly that connected with the behaviour of storms, and the formation of weather charts with a view to weather prediction. Here the catechist has practically to stand aside. In about twenty pages we meet with only eighteen distinct questions, and the tale is therefore practically told without that annoying form of interruption. And it is very well told. We feel that the author has shaken himself free from his self-imposed fetters, and is doing himself justice, and we can only regret that the earlier portion of the work is not marked by a similar freedom.

OUR BOOK SHELF.

The New Technical Educator: an Encyclopædia of Technical Education. Vol. I. (London, Paris, and Melbourne: Cassell and Co., Limited, 1893.)

THE subjects dealt with in vol. i. are as follows:—Drawing for Carpenters and Joiners, Cotton Spinning, Cutting Tools, Dyeing of Textile Fabrics, Electrical Engineering, Drawing for Engineers, Photography, Plumbing, Practical Mechanics, Projection, The Steam Engine, Steel and Iron, Technical Education, Watch and Clock Making, and Woollen and Worsted Spinning.

Taken as a whole, all these subjects are well written and illustrated copiously, several full-page plates being given. The frontispiece is coloured, and represents the scene in the Bessemer department of a steel works at night, during the process of a "blow." A very good idea is given of the wonderful pyrotechnic display.

The steam-engine is treated very much from the "heat" point of view.

Under the head of Plumbing much useful information is to be found, particularly the making of joints and bends in pipes of lead and other metals. It is usual, when making a bend in a wrought-iron lap-welded pipe, to endeavour to keep the weld on the inside of the bend, when possible, for obvious reasons. This is purely a practice which every gasfitter or plumber would naturally follow, and its omission from the paragraph is to be regretted.

The articles on electrical engineering are excellent as far as they go. The illustrations are clear and to the point; one or two of the earlier ones, however, would be improved by the addition of the lines of force.

Prof. R. H. Smith takes charge of the articles on "Cutting Tools"; needless to say they are well written, with examples taken from every-day practice in the works. The introduction of milling machinery into the engineering works of the country is comparatively of recent date, yet this method of machining work is rapidly coming to the front, and milling machinery is taking the place of the planing, slotting, and shaping machine for duplicate and general work. One great drawback to this method of working is the cost of the milling cutters; these are very expensive to make, and sometimes during the process of hardening and tempering they very often crack in the body or some of the teeth fly off. On the other hand, the quality of the work done by the milling machine is better than that from an average planing machine, less hand labour being required to finish the work.

The articles on technical education are most instructive; they cover a good deal of ground, generally taking a sensible and moderate view of the question. In the first article on this subject, the author, Mr. Henry Cunyngham, says that the object of technical education is to make good industrial workmen, and then goes on to name what are the qualities which go to make up a good workman. There is no possible doubt that apprentices to trades require facilities to study the technics of their trades, and that these facilities ought to be found in every manufacturing town, besides which, both parents and employers should make it a duty to see that the opportunities are not thrown away. On the other hand, the fact should not be lost sight of, that it is only possible to follow practice, *i.e.*, practical work, in the works.

The following chapters on this subject are by different authors, and deal with the progress of technical education in this country and abroad, then we have an elaborate description of polytechnics by Mr. Quintin Hogg, and the last chapter gives a fair idea of technical education in the colonies. All these chapters together give the reader much information about this all-important subject.

Although it has not been possible to note more of the contents of this volume, yet we can say that it is one of a series of most useful books, and if subsequent volumes are kept up to the standard of Vol. I. they will constitute a valuable Encyclopædia of Technical Education. N. J. L.

Wetterbüchlein. Von wahrer Erkenntniss des Wetters. By Leonhard Reynman. (Berlin: A. Asher & Co., 1893.)

THIS is the first number of a series of reprints of rare books relating to meteorology and terrestrial magnetism, edited by Prof. G. Hellmann, and, owing to the support of the German Meteorological Society and to a large amount of gratuitous labour on the part of Dr. Hellmann, the works, of which only a very limited number will be printed, are to be issued in a very cheap but elegant form, and will no doubt be much valued by students of those subjects and by persons interested in early literature. The *Wetterbüchlein* is the oldest purely meteorological work printed in the German language. The first edition was published in 1505, but inquiries made by Prof. Hellmann of 115 libraries in Europe have failed to discover a single copy, and of the second edition printed in 1510 only one copy can be found, viz. the one in Dr. Hellmann's library, of which a facsimile is now reprinted, together with an introduction of forty-two quarto pages, giving a most interesting and masterly account of this work and of all the other editions excepting two, of which no copy can be found. The *Wetterbüchlein*, which ran through seventeen editions in fourteen years, was exceedingly popular in its day, and contains in fourteen chapters a large number of weather prognostications, some of which are of an astrological character, but by far the greater part are based on optical and natural phenomena. The chapters are naturally of unequal value, but some of them contain results of importance deduced from a large number of actual observations. Many of the chapters have been traced by Dr. Hellmann to be based upon proverbs known to the old classical writers, and the author has also quoted freely from a work by Guido Bonatti, an Italian astrologer, which was printed in 1491, and from one by Firmin de Bellevall, a French writer, which appeared in 1485; but no clue can be found as to the origin of a chapter entitled "Das wetter zu wissen durch die vier quart des jars / als Liechtenperger setzt." If any of our readers can discover the origin of this section we shall be glad to hear of it. The *Wetterbüchlein* was, to a great extent, reprinted in various editions of the "Bauern-Practick," which appeared in the sixteenth century and had a much greater sale. It also found its way to this country, an almost literal translation appearing in "The Boke of Knowledge of Thynges Vnknown ...." published in London in 1585.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Prenatal Influences on Character.

THE popular belief that prenatal influences on the mother affect the offspring physically, producing moles and other birth-marks, and even malformations of a more or less serious character, is said to be entirely unsupported by any trustworthy facts, and is also rejected by physiologists on theoretical grounds. But I am not aware that the question of purely mental effects arising from prenatal mental influences on the mother has been separately studied. Our ignorance of the causes, or at least of the whole series of causes, that determine individual character is so great, that such transmission of mental influences will hardly be held to be impossible or even very improbable. It is one of those questions on which our minds should remain open, and on which we should be ready to receive and discuss whatever evidence is available; and should a *primâ facie* case be made out, seek for confirmation by some form of experiment or observation, which is perhaps less difficult than at first sight it may appear to be.

In one of the works of George or Andrew Combe, I remember a reference to a case in which the character of a child appeared to have been modified by the prenatal reading of its mother, and the author, if I mistake not, accepted the result as probable, if not demonstrated. I think, therefore, that it will be advisable to make public some interesting cases of such modification of character which have been sent me by an Australian lady in consequence of reading my recent articles on the question whether acquired characters are inherited. The value of these cases depends on their differential character. Two mothers state that in each of their children (three in one case and four in the other) the character of the child very distinctly indicated the prenatal occupations and mental interests of the mother, though at the time they were manifested in the child they had ceased to occupy the parent, so that the result cannot be explained by imitation. The second mother referred to by my correspondent only gives cases observed in other families which do not go beyond ordinary heredity.

"I can trace in the character of my first child, a girl now twenty-two years of age, a special aptitude for sewing, economical contriving, and cutting out, which came to me as a new experience when living in the country amongst new surroundings, and, strict economy being necessary, I began to try and sew for the coming baby and for myself. I also trace her great love of history to my study of Froude during that period, and to the breathless interest with which my husband and I followed the incidents of the Franco-German war. Yet her other tastes for art and literature are distinctly hereditary. In the case of my second child, also a daughter (I having interested myself prior to her birth in literary pursuits) the result has been a much acuter form of intelligence, which at six years old enabled her to read and enjoy the ballads which Tennyson was then giving to the world, and which at the age of barely twenty years allowed her to take her degree as B.A. of the Sydney University.

"Before the third child, a boy, was born, the current of our life had changed a little. Visits to my own family and a change of residence to a distant colony, which involved a long journey, as well as the work which such changes involve, together with the care of my two older children, absorbed all my time and thoughts, and left little or no leisure for studious pursuits. My occupations were more mechanical than at any other time previous. This boy does not inherit the studious tastes of his sisters at all. He is intelligent and possesses most of the qualifications which will probably conduce to success in life, but he prefers any kind of outdoor work or handicraft to study. Had I been as alive then as I am now to the importance of these theories, I should have endeavoured to guard against this possibility; as it is, I always feel that it is perhaps my fault that one of the greatest pleasures of life has been debarred to him.

"But I must not weary you by so many personal details, and I trust you will not suspect me of vanity in thus bringing my own children under your notice. Suffice it to say that in every instance I can and do constantly trace what others might term coincidences, but which to me appear nothing but cause and effect in their several developments.

"I will pass on to quote a few passages from letters written to me by two highly intelligent mothers, whom I asked to give me their experiences on this subject, if they had any.

"Mrs. B—— says: 'I can trace, nay, have traced (in secret amusement often), something in every child of mine. Before the birth of my eldest girl I took to ornithology, for work and amusement, and did a great deal in taxidermy too. At the age of three years I find this youngster taking such insects and little animals as she could find, and puzzling me with hard questions as to what was inside them. Later on she used to be seen with a small knife, working and dissecting cleverly and with much care and skill at their *insides*. One day she brought me the tiniest heart of the tiniest lizard you could imagine, so small that I had to examine it through a glass, though she saw it without any artificial aid. By some means she got a young wallaby and made an apron with a pocket inside which she used to call her "pouch." This study of natural history is still of interest to her, though she lacks time and opportunities. Still, she always does a little dissecting when she gets a chance.'

"I never noticed anything about P—— for some years. Three months before he was born a friend, whom I will call Smith, was badly hurt, and was brought to my house to be nursed. I turned out the nursery and he lay there for three months. I nursed him until I could do so no longer, and then took lodgings in town for my confinement. Now after all these years I have discovered how this surgical nursing has left its mark. This boy is in his element when he can be of use in cases of accident, &c. He said to me quite lately, 'How I wish you had made a surgeon of me.' Then all at once the light flashed in upon me, but, alas! it was too late to remedy the mistake.

"Before the birth of the third child I passed ten of the happiest months of my life. We had a nice house, one side of which was covered with cloth of gold roses and bougainvillea, a garden with plenty of flowers, and a vineyard. Here we led an idyllic life, and did nothing but fish, catch butterflies, and paint them. At least, my husband painted them after I had caught them and mixed his colours. At the end of this time L—— was born. This child excels in artistic talent of many kinds, nothing comes amiss to her, and she draws remarkably well. She is of a bright, gay disposition, finding much happiness in life, even though not always placed in the most fortunate surroundings. Before the birth of my next child, N——, a daughter, I had a bad time. My husband fell ill of fever, and I had to nurse him without help or assistance of any kind. We had also losses by floods. I don't know how I got through that year, but I had no time for reading. N—— is the most prudent, economical girl I know. She is a splendid housekeeper and a good cook, and will work till she drops, but has no taste for reading, but seems to gain knowledge by suction."

If the preceding cases are fully and accurately stated they seem to afford grounds for further investigation. Changes in mode of life and in intellectual occupation are so frequent among all classes, that materials must exist for determining whether such changes during the prenatal period have any influence on the character of the offspring. The present communication may perhaps induce ladies who have undergone such changes, and who have large families, to state whether they can trace any corresponding effect on the character of their children.

ALFRED R. WALLACE.

Habits of South African Animals.

THE following extracts from a letter just received from Mr. R. R. Mortimer, of Hanover Road, Cape Colony, contain some observations which will, I think, be of interest to naturalists, and therefore worth recording in the pages of NATURE.

ALFRED R. WALLACE.

"Since reading 'Darwinism,' powers of observation have unconsciously been gained by me. Day by day nature has some phenomena quite new to me, which phenomena would probably never have been observed by me if I had not had the good fortune to have digested the principles of the Darwinian Theory so obviously explained by you. From the time of reading the book till now I have observed peculiarities of organic beings in this part of the world. These observances I will relate: (1) The first observation I particularly remember was in regard to a peculiar action of a small bird, indefinitely termed by Colonials, snipe. What their specific or proper name is I cannot say, since the title of naturalist is not claimed by me. These snipe in question, or individuals of the variety, made their nests on mounds of dung which were practically the accumulated refuse of old sheep kraals. The shape of the nest was simply a hole scooped out on top of a mound. The colour of the refuse was a variegated dark brown and black. The eggs of such birds fully corresponded in colouration with the environment or surroundings. As a means of concealment, the colouration of the eggs was perfect. It required an extreme amount of careful inspection and search to detect the eggs in a nest on such mounds. When you came across the nest, you would find it was perfectly open and uncovered by any material; therefore you would presume the owners of the nest distinctly relied upon the colouration of their eggs to defy detection. But if by chance you detected a nest, and the owners *were* present, by holding yourself perfectly immovable and stationary, one bird would immediately approach its nest, and gradually cover it by scooping dust over the eggs with the action of its feet.

"This recourse to hiding its nest from view is only adopted on extreme occasions, when their sense-action gives them the knowledge that the enemy present has perceived its contents, or the nest itself. . . .

"There must be a double selective agency in this mode of concealment at work. . . .

"As far as my knowledge goes, our so defined snipe generally frequent localities where water is present. Now the *same* variety in question do make their habitat on banks of rivers, or where water is to be found; yet here have I noticed individuals of the same variety diverge from the specific character, take up a new area, if even only temporarily, where their eggs can be laid with more safety. It is an indisputable fact that the colouration of the snipe eggs is in union and harmony with the environment as a means of protection, yet here we find individuals of the same variety possessing the last possible resort of concealing its eggs—namely, covering them over with a material so as to defy any minute detective powers.

"Surely the struggle for existence must, in this case, be extremely severe, and the principle of natural selection in full activity. . . .

"(2) Having had practical experience in farming with ostriches, and their domestication, I may say a few words on them.

"Ostriches have, so to say, no means of indirectly concealing their eggs; but the only means of concealing their nest is by their personal presence. The hen does her share of sitting in the daytime, her drab-coloured plumage being in harmony with the surroundings. The cock replaces her on the nest at evening time, sitting throughout the night, and generally on to 8 a.m., his black plumage corresponding with the shades of night; therefore you have some difficulty, sometimes very great, in detecting the nest of an ostrich. . . .

"In addition to this remarkable adaptation of sexual colouration, the cock takes the *rôle* of a guard patrolling up and down some distance off the nest. When he perceives that mischief is bent upon the eggs by the approach of a person, he almost invariably charges him, and, woe betide if the person is destitute of some means of defence. To deliberately go up to a nest in the presence of its lord without some weapon or means of protection is considered by Colonials to be the height of foolishness and ignorance.

"But invariably again, on the other hand, when you have succeeded so far in reaching the nest, and handling its eggs, the cock quiets down.

"He loses all his viciousness, falls down alongside the nest, gives vent to, apparently, appeals for mercy, by continuously flapping his wings against the ground and giving forth sounds by means of his beak, of a peculiar dull clicking character.

"Domestication has made ostriches feel less fear for human beings, at the same time giving a more vigorous character to their viciousness. . . .

"Some two years ago, among a troop of ostriches that were brought down to the farm where I was gaining my experience, there was one ostrich, a male bird in every respect in its external character and colouration of plumage. It was to *all* possible appearance a cock, and yet it had been seen on two occasions to be paired by a true cock ostrich. This particular ostrich was a hen, although she had every appearance of being a cock. What explanation could you give as regards this incongruity?

"(3) About six months ago I found a peculiar bird's nest suspended from the root of a mimosa tree which overlapped a bank of ground. Before going further, I must first tell you that previous to the occasion in question I noticed the same peculiar form of nest, but it seemed so utterly impossible at the time that it could be a nest, since its structure and mode of suspension had the exact characteristics of a certain structural spider's web, that I passed it by. But on the second occasion, to make absolutely sure that I had not made a mistake, I went up and cut the nest off, with a certain length of the root to which it was attached. Imagine my surprise, when I saw that it was really a bird's nest with two eggs. Now this nest was a *perfect* facsimile of a common spider's web and home, found in the locality where I was at the time staying.

"Since it was a marvellous imitation of an insect's habitat, there must have been some corresponding necessity for such imitation. Either the nest must have been designed and constructed, so as to delude enemies by which the species was liable to be attacked, or, it was so imitated, that the materials of which the nest was made should serve as a bait, and allow the parent birds to be able to feed their young without the necessity of having to leave the nest, and so be unable to protect their young for the time being. The materials from which the nest was made were practically webs abandoned by their original owners. It was an instance of perfect imitation."

Astronomical Photography.

THE announcement (NATURE, August 10), that it is in contemplation to raise a sum exceeding £2000 for the establishment of a special photographic telescope at the Cambridge Observatory, leads me to ask whether astronomers have duly considered the facilities afforded by modern photography. At the time of my early experience of the art, thirty-five years ago, it would have been thought a great feat to photograph the Fraunhofer lines in the yellow or red regions of the spectrum, although even then the statement so commonly made that chemical activity was limited to the blue and ultra-blue rays was quite unwarranted. With the earlier photographic processes the distinction was necessary between telescopes to be used with the eye or for photography. In the former case the focal length had to be a minimum for the yellow rays, in the latter for the blue rays of the spectrum.

But the situation is entirely changed. There is now no difficulty in preparing plates sensitive to all parts of the spectrum, witness the beautiful photographs of Rowland and Higgs. I have myself used "orthochromatic" plates in experiments when it was desirable to work with the same rays as most influence the eye. The interference bands of sodium light may be photographed with the utmost facility on plates sensitised in a bath containing cyanin.

The question that I wish to ask is whether the time has not come to accommodate the photographic plates to the telescopes, rather than the telescopes to the plates. It is possible that plates already in the market may not exactly meet the requirements of the case, but I feel sure that a tithe of the sums lavished upon instruments would put us in possession of plates suitable for object glasses that have been designed for visual purposes. There would be no difficulty even in studying the requirements of a particular instrument, over or under corrected as the case might be.

A doubt may arise whether plates so adjusted would be as sensitive as those now in use. Probably Captain Abney, or some other authority, could give the required information. For some astronomical purposes a moderate loss of sensitiveness could hardly be of much consequence; for others doubtless it would be a serious matter. RAYLEIGH.

Terling Place, Witham, August 15.

The Discussion on Quaternions.

I HAVE followed with much interest the discussion on quaternions which has with more or less intermission been going on in NATURE for a long time.

It has always appeared to me that the student of physical science would better employ his time by studying the "Ausdehnungslehre" to which some of your correspondents have referred than by studying quaternions.

The wonderful work of Grassman is contained in a moderate-sized book in remarkable contrast to the two terrific volumes of Hamilton, which even Prof. Tait admits that he has not read entirely. The fact that the ausdehnungslehre could be mastered in a mere fraction of the time that would have to be devoted to the mastery of quaternions, is not however the important point.

The ausdehnungslehre seems to afford a symbolism more fitted for the expression of many recondite conceptions in physics, than anything which quaternions has to offer. Even the "Nabla" does not insinuate itself into Nature's secrets more cunningly than does the "Inneres Produkt."

Perhaps I may give an instance, which if elementary will at all events illustrate the extraordinary directness with which the different kinds of "product" reach the heart of a physical conception.

Think of a mechanical system of any kind which possesses but a single degree of freedom, think of any system of forces whatever applied to that system, and consider the question of equilibrium. The possible movements of the system form twists about one screw chain, the system of forces form a wrench upon another screw chain. Equilibrium will subsist if, and only if, the "Inneres Produkt" of the two screw chains is zero. Suppose any system whatever possessing n degrees of freedom. Dynamics teaches that mutually destructive twist velocities can be imparted to any $n+1$ screw chains about which the system can twist. Does any conceivable symbolism assign those twist velocities more beautifully than the ausdehnungslehre? Each twist velocity is the "Kombinatorisches Produkt" of all the screw chains to which it does *not* correspond.

The aptitude of other conceptions of this grand calculus for physical problems could be as readily exemplified. But I forbear. Why has not some one ere this translated into English "Die Ausdehnungslehre von Hermann Grassman" 8vo, pp. 388, Berlin 1862? ROBERT S. BALL.

Observatory, Cambridge, August 18.

A Curious Optical Phenomenon.

DR. LAUDER BRUNTON has asked me to give you an account of a very curious phenomenon witnessed from the top of Gausta mountain (height 6000 Norwegian feet) in Telemarken, south of Norway.

We were a party of two ladies and three gentlemen on the summit of this mountain on August 4.

On the morning of that day the sky was passably clear; at noon there was a thick fog. Between six and seven o'clock in the afternoon (the wind being south to south-west) the fog suddenly cleared in places so that we could see the surrounding country in sunshine through the rifts. We mounted to the flagstaff in order to obtain a better view of the scenery, and there we at once observed in the fog, in an easterly direction, a double rainbow forming a complete circle and seeming to be 20 to 30 feet distant from us. In the middle of this we all appeared as black, erect, and nearly life-size silhouettes. The outlines of the silhouettes were so sharp that we could easily recognise the figures of each other, and every movement was reproduced. The head of each individual appeared to occupy the centre of the circle, and each of us seemed to be standing on the inner periphery of the rainbow. We estimated the inner radius of the circle to be 6 feet.

This phenomenon lasted several minutes, disappearing with the fogbank, to be reproduced in new fog three or four times, but each time more indistinctly.

The sunshine during the phenomenon seemed to us to be unusually bright.

Mr. Kielland-Torkildsen, president of the Telemarken Tourist Club, writes to me that the builder of the hut on the top of Gausta has twice seen spectacles of this kind, but in each case it was only the outline of the mountain that was reflected on the fog. He had never seen his own image, and he does not mention circular or other rainbows. A. WILLE.

Christiania, August 15.

Supposed Suicide of a Rattlesnake.

THE letter of Mr. E. S. Holden, of the Lick Observatory, in your issue for August 10, describing how a rattlesnake struck its fangs into itself, when confined in a gallon jar containing water, which was inverted at intervals in order to drown it, is open to question as to its conclusion that it was a case of "deliberate suicide," for the following reasons:—

(1) That it was after "the snake ceased any attempt to rise to the surface of the water in the jar," that the blow was struck. The snake then being wholly beneath the water, would die from drowning, and not from the self-inflicted wounds caused by its poisoned fangs.

(2) That it has been proved by experiment by Dr. Weir Mitchell that the venom of the rattlesnake is of no effect upon itself, when introduced into any wound in its body. I speak from memory of an article which appeared in the *Atlantic Monthly* some few years ago. That self-insertion of the poison would make any difference is not likely.

Drowning (by the act of others) and not self-poisoning (or suicide) I take to be the cause of death in the case described.

Halifax, August 15. W. H. Wood.

Numerous Insects Washed up by the Sea.

The phenomenon referred to under the above heading in your issue of August 17 may be in part accounted for by the fact that on August 7, at many spots in the neighbourhood of Godalming (S.W. Surrey), the air was thick for several hours with swarms of winged ants. The direction of the wind was from the north-west, force moderate. Assuming the like to have taken place at other places, it is quite possible that large numbers of ants may have been carried out to sea and drowned from this region of Surrey and Hampshire.

Hunstanton, August 19. Oswald H. Latter.

THE FUNGUS GARDENS OF CERTAIN SOUTH AMERICAN ANTS.

One of the most interesting papers that has appeared during the present year, whether considered from the point of view of general biology or of mycology, is that which has recently been published by Herr Alfred Möller, nephew of Dr. Fritz Müller.[1] The work was carried out at Blumenau during the years 1890–92, and presents a clear and thorough investigation into the habits of the leaf-cutting ants and their remarkable custom of cultivating and feeding upon certain fungi. The work is introduced by a quotation from Thos. Belt's "Naturalist in Nicaragua," where the author, speaking of the leaf-cutting ants, states: "I believe . . . . that they are in reality mushroom growers and eaters." This statement Möller fully proves in the work before us. The first portion, forming the bulk of the work, is given up to the consideration of the fungus gardens of the leaf-cutting ants, and is divided into ten sections.

1. *The species of the leaf-cutting ants and their activity outside of the nest.*—Belt's description[2] of the Nicaraguan ants is quoted, and the differences between them and those of Blumenau are pointed out. The chief point of difference is that the latter form very narrow streets, travelling only in single file, and that their nests occur both in the forest and in the open. The commonest species is *Atta* (*Acromyrmex*) *discigera*, Mayr, whose workers are never more than 6·5 mm. long. Almost as common is *A. hystrix*, Latr., whose workers reach a length of 9 mm. Rarer than these are *A. coronata*, Fabr., and a doubtful form, which Möller terms *Atta IV.*

A minute description is given of a street of *A. discigera*, which was 26 metres long and about 1·5 cm. wide and high, roofed in in parts wherever possible. It led to a number of small Cupheas, whose leaves the ants were cutting. In the street could be seen a procession of loaded ants going towards the nest, and others empty-handed, going in the opposite direction. Some of the large workers run up and down the road unloaded, and act as road-menders if any accident happens to a part of the track. Other very small workers, which do not cut leaves, may also be seen carried upon the backs or even upon the loads of the actual leaf-cutters. An ant carrying a peculiarly shaped piece of leaf was watched from end to end of the track, and travelled the 26 m. in 70 minutes. The load was twice as heavy as itself.

The other species of the Atta have very similar streets. *A. hystrix* appears to work only at night.

The jaws of the ants are very strong, with serrated edges, and clash together laterally. The ant begins at the edge of a leaf, and cuts out a piece in about five minutes, revolving on one of its hind legs as a centre. When the piece is almost freed, the ant goes on to the main portion of the leaf, cuts through the last piece uniting it with the severed portion, drags up the latter, balances it on edge between its forelegs, and then, grasping it with its jaws, lifts it up above its head, so that the centre of gravity of the load is above the ant itself. It then marches off, down the stem, to the base, over the ground to the end of the street, and along this to the nest, travelling at a very uniform speed, and never letting go its load. The weight thus carried was found, on an average, to be twice that of the ant; but many were found carrying heavier loads, even as much as ten times their own weight! A street of *A. coronata* was watched for fifteen minutes, during which time 217 ants passed, carrying 3 grammes of leaves.

2. *The Nests of the Ants, and the Fungus Gardens.*—The nests of *A. hystrix* and *A. discigera* are usually below the surface of the soil, but covered, wherever necessary, with a thick mass of withered pieces of leaves and twigs, &c. They may be as much as 1½ metres in diameter. In the nests of all four species there is found, filling up the interior, a curious grey spongy mass, full of chambers, like a coarse sponge, in which the ants may be seen running about, and in which, here and there, occur eggs, larvæ, and pupæ. This is the fungus garden, termed by Belt "ant-food." It is separated from the roof and lateral walls of the nest by a clear space. The walls and roof are much thicker in winter than in summer; one nest examined had a roof 25 cm. thick and wall 40 cm. Photographs are given in the original paper, showing the appearance of the mushroom garden.

3. *Investigation of the Gardens. The Kohl-rabi clumps.*—The garden consists of two parts, differently coloured, but not very sharply marked off from one another. The older part is yellowish-red in colour; the newly-built portions, forming the surface of the garden, are of a blue-black colour. It is this part which is of the greater importance to the ants.

The garden is found, on examination, to consist of an immense conglomeration of small round particles of not more than ·5 mm. in diameter, of a dark green colour when quite fresh, then blue-black, and finally yellowish-red. They are penetrated by, and enveloped in, white fungus hyphæ, which hold the particles together. These hyphæ are similar throughout the nest.

Strewn thickly upon the surface of the garden are seen round white bodies about ·25 mm. in diameter; they always occur in the nests, except in the very young portion of the gardens. They consist of aggregations of peculiar swollen hyphæ, and are termed by Möller the "Kohl-rabi clumps." The hyphæ swell out at the ends into large spherical thickenings, about 10–24 μ in diameter (the ordinary hyphæ are 5–8 μ thick), filled with richly vacuolated protoplasm like the ordinary hyphæ. These clumps of "Kohl-rabi" are only found on the surface of the garden, and form the principal food of the ants. A microscopic examination of the particles of which the garden is composed shows that they contain remains of leaves; bits of epidermis, stomata, spiral vessels, &c., occur in them.

4. *The Importance of the Garden to the Ants.*—If a nest be broken into and the garden scattered the ants collect

[1] "Die Pilzgärten einiger südamerikanischer Ameisen." Heft 6 of Schimper's "Botanische Mittheilungen aus den Tropen." (Jena: G. Fischer, 1893.)

[2] "Naturalist in Nicaragua," p. 71.

it as quickly as possible, especially the younger parts, taking as much trouble over it as over the larvæ. They also cover it up again as soon as possible to protect it from the light. A nest, 1 metre × 50 cm. was opened, and in twenty-four hours the ants had put on a new roof 10 cm. deep. They also carry the nest with them upon their migrations

5. *The Use of the Garden: its Construction and its Tendance observed in Captivity.*—Some ants' nests were placed under a bell jar and supplied with leaves; they made no use of them and presently died. If they were supplied with a piece of "garden," they rebuilt it and covered it so far as they could. It was seen to shrink from day to day, the ants bringing out the old pieces and adding them to the wall; finally it was exhausted and the ants died. Others were starved for five days, and then supplied with a bit of garden; they at once began to eat the Kohl-rabi clumps. It was found by this means that each species of Atta will eat the Kohl-rabi of the other three as well as its own. Finally, by supplying the ants with bits of garden, a damp sandy floor, and fresh leaves, they were induced to build in captivity. The dish in which they worked was covered by a glass lid, and when this was covered with a dark cloth or otherwise kept dark, the ants built under it without covering the garden. In this way the whole process was observed. An ant bringing in a piece of leaf proceeds to cut it into halves, repeating the process till it has got a very small piece left, which it holds between its fore feet and turns round, crushing it in its jaws until the whole is reduced to a round ball of pulp about ·25 mm. thick. This it then takes and adds to the garden. So well is the kneading performed that no single cell remains uninjured, and it was observed that the hyphæ of the fungus grew through and round one of these particles within a few hours. Belt supposed that this process was performed by the small workers above-mentioned, but it is not so, as we have just seen. The small workers perform the function of weeding the garden, and this is so well done that a portion of it removed and grown in a nutrient solution gives a perfectly pure culture, not even containing bacteria!

6. *Development of the Fungus after removal of the ants; the conidia, "pearl-hyphæ," and strand-swellings. Result of the artificial culture of the Fungus.*—If a portion of garden be left to itself in darkness, the ants having been removed, aerial-hyphæ develop in a thick mass several centimetres high, with many anastomoses; the Kohl-rabi clumps are used up in the process, apparently supplying material for it. The formation of conidia now takes place all over the mass. From a hypha there buds out a lateral projection, which bears branches arranged roughly in whorls: upon these are again borne whorls of small club-shaped branches, from whose ends are abstricted rows of conidia, whose diameter is 2 μ; there are, as a rule, not more than ten in a row. Occasionally the formation of the strings of conidia occurs not only on the final branches, but also on those of the preceding order. After the conidia are formed the mass collapses (about the fifth day).

About the third day a careful search reveals among the ordinary hyphæ a few which are covered, as with rows of pearls, with small spherical lateral protuberances. These "pearl-hyphæ" arise from the ordinary ones. The cavity of the "pearl" is in direct communication with that of the hypha itself, and contains protoplasm. In connection with these there occurs a second type of conidia formation, distinguished by Möller as the "weak" formation. There is no preliminary branching, the conidia being abstricted from the ends of the pearl hyphæ, or plain hyphæ in connection with them. The end of the hypha swells up and bears the conidiophores. The chains generally consist of at least twenty conidia.

Still a third form of hypha is to be found. Sooner or later there are observed on the garden thick white strands, which on examination are found to consist of hyphæ, which look like rows of beads, or yeast-chains, and are much bent, branched, and twisted. From these there arise pearl hyphæ, or we may find pearls upon these hyphæ themselves. These peculiar hyphæ arise first of all as "pearls" on ordinary hyphæ, and then a process of budding goes on, just like that which gives rise to yeast chains. The "pearls" might be looked upon as homologous with these lateral swellings of hyphæ, but there is also another view, that they represent rudimentary conidiophores. It has been seen above that the conidiophores in the "strong" conidia formation are not always confined to the ends of the hyphæ, but may at times appear further back, and it is suggested that originally they were borne anywhere upon the hyphæ, and subsequently restricted to the tips, the "pearls" then representing rudimentary conidiophores. The "pearl" hyphæ and weak conidia formation are usually found in connection with these swollen strands, and on one or two occasions a connection was found with the strong conidia formation.

When a few ants were left with a large piece of garden, they did their utmost to prevent the formation of these aerial hyphæ, &c., biting them off as they appeared, but gradually the fungus gained the upper hand of them. Proceeding now to the results of culture in nutrient solutions, the strong conidia germinate and give rise to hyphæ which ultimately bear strong conidia again. Never did the "weak" form appear, but very often from the main hypha there were given off lateral branches, some of which developed into rows of beads, like the hyphæ described above, and others swelled up at the ends just like the Kohl-rabi. The cultures being pure, these formations could not be pathological, produced by bacteria, as is sometimes the case.

Similarly the weak conidia gave rise only to conidia like themselves. Pearl-hyphæ were occasionally formed, and rarely the peculiar hyphæ like rows of beads.

When one of these forms was grown in one culture drop, and bent over into another drop, in which the other form was, the two anastomosed freely, showing that they belonged to the same plant.

When a portion of Kohl-rabi is grown in the solution it gives rise to ordinary hyphæ, which ultimately produce a new crop of Kohl-rabi. On one occasion it gave rise to pearl-hyphæ and weak conidia.

To sum up, the fungus has two conidia forms, which develop upon the garden in the absence of the ants. The mycelium shows a strongly marked tendency to the formation of swellings and protuberances, which appear in a different form, more or less distinctly marked. One of these, which has probably reached its present form under the cultivation and selection of the ants, is the Kohl-rabi.

7. *Discovery of the Highest Fructification of the Fungus.*—It being evident that the fungus was either a Basidiomycete or Ascomycete, attempts were made to obtain its principal fructification by cultivation, but in vain. A fortunate discovery, however, was made of a nest which had a huge red Amanita-like fungus growing out of it. This was found to belong to the genus *Rozites*, and the species was named *R. gongylophora*. The development of the basidia, &c., is given in detail, but need not be gone into here. Cultivation of the spores showed that this was indeed the fructification of the Kohl-rabi-forming fungus.

10. *Plants attacked by Leaf-cutting Ants.*—These were found to be very numerous, and no rule could be formulated as to the operations of the ants. On one day they would strip one plant and the next day leave it untouched, or *vice versâ*. An interesting case was observed in the cold weather. An army of leaf-cutters was found stripping a Cecropia, though the latter was inhabited at the time by its protecting ants! The latter appeared to be too numbed by the cold to go out and fight.

THE GARDENS OF THE HAIRY ANTS.

While working at the preceding it was discovered that somewhat similar fungus gardens occur in the nests of *Apterostigma.* Four species were studied. All have the same fungus, belonging apparently, however, to a different genus from *Rozites.* These hairy ants live in decaying wood and have small gardens 4-8 cm. in diameter, built of bits of wood-fibre, beetle-dung, &c. The chief point of interest is that though all have the same fungus yet all have not cultivated and selected the Kohl-rabi to the same degree. *A. Wasmanni,* Forel, has a well-developed type with large spherical swellings on the ends of the hyphæ. The others have Kohl-rabi of a much lower type, the hyphæ being only slightly swollen into a club shape, and they are not aggregated into regular groups.

It was, as usual, found impossible to obtain by artificial culture the highest fructification of the fungus, so its systematic position is still undetermined.

THE GARDENS OF CYPHOMYRMEX.

This genus of ants is closely related to the two preceding, and the two species examined (*C. auritus,* Mayr, and *C. strigatus,* Mayr) are also fungus-growers. Both form nests like those of Apterostigma, and use similar material in the garden. The two species have the same fungus, but *C. strigatus* obtains far finer Kohl-rabi than *C. auritus,* just as we have seen to be the case with the species of Apterostigma. It is thus pretty evident that the large size of the best Kohl-rabi must be due to selection and cultivation on the part of the ants.

The concluding pages of the work are taken up by a discussion of the mycological results of these investigations, for which reference must be made to the original. The work is illustrated by beautiful plates, and forms as a whole one of the most fascinating contributions to botanical literature that have been made for many years.

JOHN C. WILLIS.

A FEW REMARKS ON INSECT PREVALENCE DURING THE SUMMER OF 1893.

WE are hearing a great deal just now of unusual amount of insect presence, and there appears no reason to doubt that such is very much the case, although for scientific use we need much more of reliable report than we possess as to what kinds of insects are noticeably more present than in seasons of ordinary meteorological conditions, and also we need observations as to what kinds may be unusually absent.

So far as my own acquaintance with the subject (which is mainly in reference to amount of presence of crop insects) allows me to judge, these unusually large amounts where they occur—for the superabundance does not affect all kinds—may be attributed to weather influence acting either directly on the development of the insects themselves, or so affecting the state of their crop-food-plants as to induce the conditions which we know well by the agricultural experience of many years are favourable to establishment of infestation.

The important preliminary as to there having been really such a definite deficiency in rainfall as to amount to what may be called "a drought" over England and Wales, we have stated shortly in the *Monthly Meteorological Magazine,* of Mr. G. J. Symons, F.R.S., No. cccxxxi., p. 98, as follows :—"Assuming that the twenty-four stations fairly represent England and Wales, we find that in March the rainfall was only one-third of the average, in April one-sixth, in May three-quarters, and in June two-thirds." Mr. Symons further points out that "this, of course, is taking the country as a whole ; at many individual stations the results would be much more striking, *e.g.* at Bodmin in the three months" (March to May) "only one fifth of the average fell."

Amongst insect attacks especially subject to increase by stunting of growth, or over-maturation of sap of thei food plants, are those of the Aphides or Plant Lice which have been—so far as my own contributors' report show—unusually early and prevalent this year. They were forwarded on mangolds from Devonshire almost a soon as there could be said to be good accommodation for attack on the leafage, and turnips and cabbage leafage damson early in the season, and larch later on the bor ders of England and Scotland, were some of the tree and food plant habitats which were exceptionally afflicted These prevalences agree with the rule of Aphis life laid down by Mr. G. B. Buckton, F.R.S., our great authority on Aphis life. In drawing attention to the abnormally rapid increase of Aphides under some circumstances, he accounts for it by maturity (*i.e.* power of reproduction taking place earlier in the life stage where from various causes inducing want of supply of nutriment, structura changes occur consequently on these in the larvæ of th Aphides subsequently born. (See "Brit. Aphides," b G. B. Buckton, F.R S., vol. i. p. 72).

Besides the above reasons for increase, we have als the negative reason of absence of destruction by goo drenching rains to wash off and often to drown th enemy. One of my correspondents wrote me that he ha been doing this or that, but the best help was the we come rain.

The above may be taken as a type of one way in whic weather influence acts ; in the case of wasps, which pop larly represent much of insect presence to the world a large, we have another set of influences.

Our recent drought began in March. In many year we have the most variable weather at this season and the queen wasps, the foundresses of the comm colonies, being tempted from their winter localities o hybernation by a day or two's warmth, are caught, it ma be, by heavy rain, or by snow, or by frost, and peris This year weather was more favourable to them, and w had not the drenching rains which in an ordinary ye put an end to many an embryo nest with its few grub whether in ground or hedge. The first commencemen formed of a tiny piece of paper, in shape like an um brella, with beneath it a pendant ending in a club forme of a few cells, each with its egg or young maggot tenan is delicate in the extreme. If the cavity in which it placed in the ground is flooded, its destruction is certai or if in storms the foundress cannot return to feed th young family they must perish.

In the case of wasps, probably weather influence which affect amount of any particular kind of food are a little troublesome as to any insect. All who at all stu their habits are aware that flesh, fish, insects to a larg amount, and fruit to utter rapacity of consumption, a constantly utilised by them for their own special suppo or that of the maggot family. To what extent the ad wasps may feed on other than vegetable matter I cann say, but dissection and examination of the undigeste food in the blind pouch of the food canal of the larv wasp has shown this to consist of remains both of anim and vegetable matter ; in the record before me chiefly insect *débris.* Their varied kind of food and their wo derful adaptability of instinct in making adverse c cumstances suitable for the household needs, make th wasp family when once established, most prolific pests

The great prevalence of what are called surface cat pillars, that is, the larvæ of various kinds of Agrotis the roots of various kinds of field crops, gives an examp of increase of presence of the Lepidoptera, under circu stances favourable to the development of the imago fr the chrysalis, and subsequently to the pairing of t moths and successful egg deposit. In wet and ch weather, when the moths hang about torpidly, a certa proportion of them get drenched, so that their wings a of little service ; the larvæ are injured in different wa or disease induced, much influencing amount of presen

In the past season such attacks as that of the great caterpillars (four inches or more in length) of the Lappet Moth, the *Gastropacha quercifolia* scientifically, to apple leafage; or again, the presence of caterpillars of the little *Pyralis glaucinalis* might reasonably be supposed to be influenced by weather. In the first case, the great size of the larva feeding on the leafy twig exposes it much to alternations of weather, and in the second, where, as in the samples sent me, the infestation was located in the outer part of fodder stacks, the penetration of wet which might soak the filmy cocoons with their developing contents, would cause conditions very different to the long-continued appearances of the present summer.

To go through the different orders of insects, specially represented, or the different dates and amounts of their appearance on the crops, would be too long here, but I can safely say that whilst the drought lasted I had constant applications regarding insect appearances, including a much greater variety than usual of kinds little observed in ordinary years, and in some cases unusual amount of presence of our common kinds.

Various representatives of the Acarina, as the currant, pear, and plum Phytopti were of course largely noticed, as also the Phytopti (or gall mites) of the hazel buds, of which the galls loaded the hazel boughs in this neighbourhood early in May to a degree I have never before seen. The kind of (so-called) "red spider" (*Bryobia prætiosa*) which ordinarily is chiefly found on ivy, extended its injurious presence so widely to gooseberry leafage as to necessitate careful, and happily successful, measures to get it under.

Why, with all this, various crop insect attacks were less reported than customarily remains uncertain. Corn Aphides as yet have not been complained of. Possibly this is by reason of the heat hardening the ears so that they were in a condition to withstand attack before the Aphides arrived on the heads to endeavour to pierce into them with their suckers. In countries where the climatal conditions can be counted on, this point (of arranging date of crop so as to protect itself from attack) is one of the regular methods of prevention. Another infestation which threatened to be very troublesome, but of which the second brood did not make any noteworthy appearance in various places, is that of the mustard beetle. Why this should be so I am as entirely at a loss to explain as the crop inspector who reported the state of things to me.

Various other absences of attack remain also unexplained, but are duly noted for possible future service in agricultural entomology.

So far as I can gather from contribution of my own correspondents, or other accessible sources of information, I should consider that such extra amount of insect presence as has occurred, has been owing to weather influence. We have had earlier and more numerous development of many kinds, and also in the case of various common crop insect pests, the hardness of the soil, and other conditions incident to drought, which made it totally impossible to bring either stimulating dressings, or mechanical measures to bear, necessitated our permitting increase to go on unchecked in some cases, and in some, though the caterpillars just below the surface of the ground necessarily did not themselves multiply, their unattainable legions swelled the numbers of observable pests, and probably will supply us a plentiful brood of moths for further continuation of species.

There does not appear to be any reason from previous circumstances, or from importations, to consider that we were suffering from other than the ordinary attacks, which, in a changeable climate like ours, must be changeable in their amounts; at least, so it appears to me from such an amount of report as I possess.

ELEANOR A. ORMEROD.

THE GREAT HEAT OF AUGUST 8 TO 18.

AN extraordinary wave of high temperature passed over this country between the 8th and 18th of this month, which has also been remarkable on account of the continuance of the heat during several consecutive days. High temperatures were experienced in all parts of the United Kingdom, but more especially in the southern and eastern portions of the country. The following table shows their distribution as represented by the stations included in the *Daily Weather Report*:—

Stations.	Days with temperature of 75° or more.	Days with temperature of 80° or more.	Days with temperature of 85° or more.	Days with temperature of 90° or more.	Days with temperature of 75°–90° or more.	Maximum temperature.	Date.
Leith	5	—	1	—	6	85°	15
North Shields ...	3	2	—	—	5	83	18
York	5	4	1	—	10	86	18
Loughborough ...	1	4	5	1	11	91	18
Liverpool	4	2	1	—	7	85	17
Parsonstown	5	2	—	—	7	82	14 and 16
London	—	4	4	3	11	93	18
Oxford	4	2	5	—	11	89	17 and 18
Cambridge	3	2	4	2	11	92	18
Jersey	4	4	3	—	11	89	17

A glance at this table shows that at Loughborough, Oxford, Cambridge, London, and the Channel Islands the temperature reached or exceeded 75° on every day of the period in question, the maxima reaching 91° at Loughborough on the 18th, 89° at Oxford on the 17th and 18th, 92° at Cambridge on the 18th, 93° in London on the 18th, and 89° at Jersey on the 17th.

At Greenwich the temperature exceeded 80° on each successive day from the 8th to the 18th inclusive, the highest readings being 93° on the 16th, 94°·2 on the 17th, and 95°·1 on the 18th. The last reading has only been exceeded twice at any time of the year during the last half-century, viz., 96°·6 on July 22, 1868, and 97°·1 on July 15, 1881. The highest reading in the sun during the eleven days in question was 146°·2 on the 18th, but this temperature was slightly exceeded in June last. Mr. Symons states that, on the 18th instant, the thermometer at his station at Camden Town registered 93°·6, which has only once been exceeded during thirty-six years (1858–93), viz., on July 15, 1881, when it read one degree higher; the present is the only year with a maximum shade temperature above 90° for three consecutive days. On the night of the 17th instant the minimum temperature in South London was as high as 72°, being rather above the average maximum temperature for the month of August, and the daily mean, as deduced from the maximum and minimum readings in the *Daily Weather Report* for the 18th, was 82°·5; this mean value is probably the highest on record since trustworthy observations have been taken. In a valuable paper recently read by Mr. Ellis before the Royal Meteorological Society, the average mean temperature at Greenwich for that day is given as 62°·5.

On the Continent the highest readings quoted in the *Daily Weather Report* were 102° and 106° at Rochefort in France on the 13th and 14th instant, while the maximum readings there reached or exceeded 90° on seven consecutive days. In the South of France the temperature exceeded 80° on each day of the period in question, 100° being recorded at Biarritz on the 17th.

The Weather Charts published by the Meteorological

Office during this period show that the conditions were mostly anti-cyclonic, both over this country and the Continent, with the exception of a depression in the south-west, which caused some sharp thunderstorms on the 9th and 10th. On the 18th another depression appeared off our north-west coasts, causing a gale in those parts, while strong winds and lightning occurred generally, with heavy rain in the west. These conditions checked the excessive heat; on the 19th the maximum temperature in London was 15°, and at Paris 25°, lower than on the previous day.

A SENSITIVE SPHEROMETER.

THE ordinary spherometer has three arms carrying three fixed points, with a point moved by a screw in the centre. This form is an improvement on the original spherometer invented by Andrew Ross, and for which the Society of Arts gave him a silver medal in 1841.

A description of Ross's instrument is given by Holtzapffel, vol. iii. p. 1271 of his work on "Turning and Mechanical Manipulation," extracted from vol. liii. of the Transactions of the Society of Arts. This instrument could measure to $\frac{1}{1000}$ of an inch, and by estimation half this amount. An ordinary spherometer, with a screw of $\frac{1}{100}$ of an inch pitch and head divided to hundredths, will measure to $\frac{1}{10000}$ of an inch.

I pointed out in vol. l. page 145, of the Memoirs of the Royal Astronomical Society that the sensitiveness of the ordinary spherometer was much increased by placing the screw not in the centre, but in one of the arms in place of one of the fixed points; this at once increased the sensitiveness of the screw in proportion to the distance of the screw from the nearest fixed point, and this fixed point from a line joining the other two fixed points.

The improvement I wish to bring before those interested in spherometers by this note, is the extension of this principle, for by carrying the middle point much nearer the line joining the other two, a proportionate increase of sensitiveness is obtained.

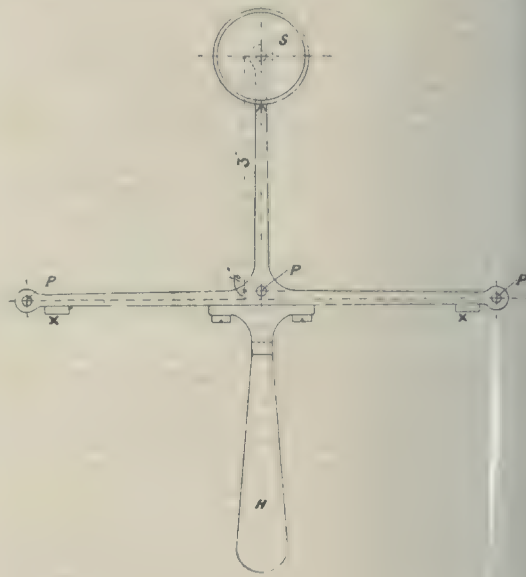
In the case of an instrument I have made on this plan I have increased the sensitiveness thirty times, the distance from the middle point to the screw being three inches, and the distance of the point from the line of the other two being $\frac{1}{10}$ of an inch; with a screw of one hundred threads to the inch and a head divided to hundredths, the ordinary form of instrument will read to $\frac{1}{10000}$, but on the plan I give, the same screw will measure $\frac{1}{300000}$ of an inch.

There is an additional advantage in this form, that the curvature of a part nearly in a line is measured, so that cross measures can be taken.

The form of the instrument is not symmetrical, and it requires to be balanced, so that when the screw is raised it will be possible to estimate the frictional contact of the outside points when the middle one is taking the weight. This balancing is easily done by adding a handle to the part opposite the arm carrying the screw; in practice it is found that this handle is of the greatest value in keeping the heat of the hand from the instrument, as even with the ordinary instrument, holding it for a short time in the hand alters the readings materially.

It is of great advantage to have on the arms carrying the two outer pins two pieces of wood or ivory projecting not quite as much as the measuring points, so that by tilting the instrument up these two pieces come first into contact with the surface to be measured, then by gradually raising the handle the points are brought gently into contact. The figure is a plan of this spherometer, and shows the position of the three fixed points P P P with reference to the measuring screw S, and the position of the balancing handle H with reference to the unsymmetrical arm carrying the measuring screw; X X are the projecting pieces already mentioned.

The movement of the screw being so large for a slight curvature, this instrument is more particularly useful for measuring the slight curvatures of so-called plane mirrors,



PLAN

for which, indeed, it was designed. To make it available for measuring differences between parts of a curved surface of considerable curvature the middle pin should be a screw capable of movement to, and clamping, in a position, that will allow the measuring screw to work.

A. A. COMMON.

JEAN DANIEL COLLADON.

DANIEL COLLADON, the celebrated physicist and engineer, died on June 30, at Cologny, near Geneva.

Colladon was born at Geneva, December 15, 1802. He belonged to a Protestant family from Berry, which removed from France, in the middle of the sixteenth century, on account of religious persecutions, and found refuge in Calvin's town. Many a distinguished magistrate came from this family, amongst others the learned juris-consult, Germain Colladon.

While still quite young Colladon proved to be wonderfully intelligent, and had a remarkably observant mind.

He went through the College and then the Academy of Geneva, which at that time had, among its professors, A. P. de Candolle, M. Aug. Pictet, Th. de Saussure and Prevost. His liking for science could not but develop itself in contact with these eminent men, whose esteem he soon gained.

At the age of ten years he made friends with Charles Sturm, who became a noted mathematician, and was on later occasions his fellow-worker. His inventive nature and talent for experimental inquiry turned itself above all to physics and its mechanical applications.

He was just twenty-two when he received from the Society of Science of Lille a first prize for the invention of a new photometer. At twenty-three he went to finish his studies at Paris. He lived there for about ten years, leading a simple life, almost entirely devoted to work.

He was received in a most flattering manner for such a young man by the pleiades of celebrated men, which the great town then possessed; Arago, Dulong, Fresnel, Fourier, Ampère. He made true friends with many of them, and had the honour of being a fellow-worker of the two last. At Paris he found the old friend of his childhood, Sturm, with whom, in 1826, he made the wonderful experiments on the Lake of Geneva, relating to "the velocity of sound in water," which united their two names so admirably in all treatises on physics, and which won for them the grand prize of the Institute of France.

By the side of these classical researches, Colladon's first works deal chiefly with electricity. In 1826 he published his experiments made at the College of France, with a galvanometer of his own invention, on the magnetic actions which ordinary electrical machines, Leyden batteries, and atmospheric electricity produce on the magnetic needle. He studied the electrodynamic actions with Ampère, and the conductivity of thin bodies for heat with Fourier.

The celebrity which he had acquired for himself at Paris by his works led to his being asked by the founders of the Central School of Art and Manufacture to join them, and to give a special course of lectures on the steam-engines and their use, which he did with much success from 1831 to 1834. He also made numerous researches and inventions relating to steam-engines. In 1844 the Lords of the English Admiralty adopted a dynamometer which he invented to measure the effective power of steam-engines for navigation, and which he was charged to make at the Royal Arsenal of Woolwich at the cost of the Admiralty.

In spite of the honourable place which he had attained at Paris in the world of science and industry, Colladon, was so attached to his country, that he gave up the many advantages which would accrue from a residence in France, and settled at Geneva in 1834. He proved himself on many occasions most useful in the debates of the little Republic, and was made Professor of the Academy in 1839.

In 1852 he rendered to the industry of his country the great service of representing it at the first Universal Exhibition in London, where he was delegated by the Federal Council as Commissioner for Switzerland.

He took part in two juries relating respectively to physical instruments and clocks. The most diverse branches of industry excited the interest and research of his fruitful mind. One to which he gave most of his attention was illumination by gas. In 1844 he was appointed engineer of the new gas company at Geneva. He invented a great number of improvements in gas-lighting, and the wonderful competence that he acquired has contributed largely to establishing a great number of enterprises of the same sort both in Switzerland and abroad. It was on this account that he was charged to superintend the installation of the Gas Society at Naples.

Hydraulics occupied him on many occasions; he studied the water supply of towns, and invented floating hydraulic wheels with the paddles below. It was he who discovered the ingenious way of lighting a liquid tube from within, by introducing, as it were, with the water a luminous ray, which remains imprisoned by the effects of totally multiple reflections, and illuminates the whole length of the liquid cylinder. The luminous fountain, or, as it is often called, "the Colladon fountain," originated from this delicate experiment. It formed one of the most beautiful ornaments at the Universal Exhibition at Paris, and was tried on a larger scale for the first time at the exhibition of Glasgow in 1884.

But these are not the inventions which render great the name of their inventor; the one which merits this honour, and to which the name of Colladon must ever be united, is that of the use of compressed air for the transference of energy. Profiting by the resources which he had at his disposal as engineer of the gas works at Geneva, from 1849 he made essays on the circulation of compressed gas in pipes, and he demonstrated the possibility of transmitting with economy a considerable energy for a long distance in narrow pipes. It is easy to understand the immense importance in the construction of long tunnels of transmitting energy by compressed air, for with the impulse given to the boring machine, fresh air is brought at the same time to the workmen at the end of the deep galleries. It is this idea, as simple as it is beautiful, which constitutes Colladon's claim to glory; this invention which must immortalise his name: it is this which makes it possible to construct the great subterranean passage which honour our generation, and which have made him one of the benefactors of our time. After the first studies for the tunnel of Mont Cenis, in December, 1852, he gave an excellent memoir on the subject to the Financial Minister of the Italian State, which was followed by a request for a patent for the new processes.

This important memoir, transmitted by the Italian Government to the Royal Academy of Science at Turin, was the object of a special report addressed to the Minister, and it concluded thus:

"The author does not limit his memoir to a simple description of the proposed scheme, but he shows the applicability by theoretical considerations. The commission recognises above all the vast importance the inventions of Monsieur Colladon could be in hastening the construction of the railways destined to cross the Alps." The splendid invention of Colladon was applied with much success by the Italian engineers at the construction of the Mont Cenis tunnel, and it made its reputation there, but all the honour belongs to the discoverer. If Colladon had not the pleasure of making the first applications of his invention, and if he had to leave to others the honour of making the first sub-alpine tunnel, he was able at least to give his ideas full development in the making of the St. Gothard tunnel, by the installation of the powerful compressors at Goeschenen and Airolo, which he executed for the enterprise directed by L. Favre.

Colladon was one of the first specialists in the art of constructing tunnels. It is owing to this that in 1878 he was made a member of the committee connected with the tunnel under the Channel. He was also very busily occupied studying out the boring of the Simplon.

We cannot in this short notice give a complete idea of the greatness, and fruitfulness of Colladon's career. Suffice it to mention his researches on the electricity of the torpedo, atmospheric electricity, the effect of lightning on trees, snow and hail, waterspouts, the use of steam for putting out fires, and on the terraces surrounding the Lake of Geneva.

Colladon had such a many-sided mind, that he could interest himself with the most diverse questions, and he studied them all with remarkable care and conscientiousness. Absolutely disinterested, he worked for the advancement of science, without pushing his inventions for his own profit. On the contrary, he was always at the service of others, and always ready to help them with his advice and assistance without any remuneration.

He was a great worker and was willing to assist others until the last years of his admirable life. He died at the age of ninety-one, preserving nearly to the last the use of his fine and noble faculties. His reputation had extended itself far and wide, and a great number of learned societies of all parts of the world counted him among the number of their members.

Ed. Sarasin.

NOTES.

We learn that Dr. J. W. Gregory arrived at Mombasa on August 19, after a successful expedition to Lake Baringo. He returned *via* Likipia and Mount Kenia, and ascended the latter to a height of more than 17000 feet. Dr. Gregory has explored the glaciers and the head-streams of the Tana, and the watersheds between the Tana and Athi rivers.

THE death is announced of Prof. G. W. Coakley, who for thirty-three years occupied the chair of mathematics and astronomy in New York University. He was born on the island of St. Bartholomew on February 22, 1814, entered Rutgers College in 1832, and graduated in 1836. In 1843 he was made professor of mathematics and astronomy in St. James's College, Indiana, where he remained until 1860, when he accepted the same professorship in New York University, filling the chair vacated by Prof. Loomis, who had gone to Yale University. He held this chair in New York University until his death, and was engaged in active teaching until his 77th year.

A REUTER'S telegram from Halifax, Nova Scotia, states that a terrific hurricane swept over the Maritime Provinces on August 21, and was the worst that has occurred since the great storm thirty years ago. In Halifax a vessel was sunk in dock, trees were uprooted, and the electrical systems were wrecked.

ON August 25 Prof. J. Victor Carus, the editor of the *Zoologische Anzeiger*, will celebrate his seventieth birthday. In honour of the occasion, the current number of that journal contains a remarkably fine portrait of the renowned zoologist.

THE Board of Agriculture notify that arrangements have recently been made by which the latest issues of the Ordnance Survey maps on the 1 in. and 6 in. scales have been made available for inspection by the public at the offices of the Board, at 3, St. James's Square. Changes in the boundaries of boroughs, of local government districts, and of parishes will be recorded on the 6 in. maps as soon as possible after they have been authorised, and a complete set of the index maps and indices of all Ordnance Survey maps and publications will be kept in hand for reference. It is believed that the facilities for inspection thus afforded will be found to be of general public utility.

THE *Times* gives some details received from Japan with regard to the recent volcanic eruptions in the Fukushima district, in the mountains of which Bandaisan, where there was a destructive eruption a few years ago, is the chief. The disturbances began with an earthquake early in the afternoon of June 4, which was followed by an eruption of Azuma-Yama the next morning. Other peaks in the neighbourhood became active, and the showers of stones and ash did much damage, especially to the mulberry trees of the district. It was decided to investigate the mountains, and two members of the geological bureau of the Agricultural Department were despatched from the capital for the purpose. They ascended Azuma-Yama very early on the morning of June 6 with the view of making observations in the immediate vicinity of the craters, and the same night reported to the authorities in the capital that, when they ascended, volcanic ash was falling and strong puffs of black cloud were escaping from time to time. They were able to make a circuit of the craters, from one of which dense volumes of vapour and ash were being emitted and from another heated air only. Whenever part of the sides gave way and fell in, the volume of vapour increased and a rumbling noise was heard. Heated fragments of rock were thrown out from time to time. On the morning of June 7 two students of the University of Japan and two engineers ascended the volcano. A violent eruption occurred while the party were approaching the crater. A dense column of gas arose, and was accompanied by a shower of rock fragments. After the explosion it was found that the two engineers had been overcome by the fumes. Attempts were made to rescue them, but they unfortunately failed. It was not until the following day that the neighbourhood of the crater could be searched and the bodies recovered.

THE *Journal* of the College of Science, Imperial University, Japan, Vol. V. Part IV., contains a paper by Prof. B. Koto "On the Cause of the Great Earthquake in Central Japan, 1891." Prof. Koto has examined a great line of fault which traverses a distance of 112 kilometres from the Kisogawa to the city of Fukui, through the Neo valley, cutting the hills, mountains, and plains alike with remarkable regularity and sharpness. He is of the opinion that the entire region on one side of the line of fault moved downwards in October, 1891, and was also shifted horizontally towards the north-west for from one to two metres along the plane of dislocation, thereby causing the earthquake.

MR. J. D. McGUIRE has, during the last two years, been endeavouring to reproduce aboriginal methods of work, chiefly in stone, with tools of stone, wood, and bone, such as are found in village sites in America and Europe, as well as with tools found in graves, and those used by races living in savagery. He describes his experiments in a paper "On the Evolution of Working in Stone," that appeared in the *American Anthropologist* for July. The experiments show that the art of grinding and battering stone must have preceded that of chipping, and that neolithic implements which are supposed to have taken years to fashion were really but the work of a few hours.

WRITING in the *Journal* of the Polynesian Society, Miss Teuira Henry, of Honolulu, says that a strange ceremony used to be practised by the heathen priests at Raiates, but can now only be performed by two descendants of priests, Tupua and Taero by name. This ceremony consisted in causing people to walk in procession over a hot earth-oven, without any preparation upon their feet, whether barefooted or shod, yet upon their emergence they did not even smell of fire. The ovens are frequently thirty feet in diameter, and are filled with roots of the *ti*-plant (*Dracaena terminalis*) and short pieces of *ape*-root (*Arum costatum*). It is hoped that some one will endeavour to solve the mystery of the feat while those men who practise it still live.

THE U.S. National Museum have published a report by Mr. Romyn Hitchcock on "The Ancient Burial Mounds of Japan," illustrated by ten excellent plates, mostly reproduced from original photographs. Mr. Hitchcock visited Japan with Mr. W. Gowland, who has spent several years in the study of the Japanese mounds. One of the earliest modes of burial in Japan was in artificial caves, hewn out of the solid rock on hillsides. It has been said that the early Japanese were cave-dwellers, but Mr. Hitchcock thinks this is very doubtful, for the reason that natural caves are not found where the history of the people begins, in Idzumo and Yamato. The examination of both natural and artificial caves indicates, at any rate, that the Japanese have not been cave-dwellers since their migration to Japan. Four distinct methods of burial have prevailed in Japan at different periods, which are distinguished by Mr. Hitchcock as follows:—(1) Burial in artificial caves. (2) Burial in simple mounds of earth. (3) Burial in mounds with rock chambers, or dolmens. (4) Burials in double mounds, or imperial tumuli. The chronological sequence of these different modes of burial is a matter of speculation, but, in all probability, the caves preceded in time the rock-built dolmens. No inscription remains, however, to enable ethnologists to solve the origin of the custom of cave-burial. A variety of articles were obtained from the mounds by Mr. Hitchcock, notably vessels of pottery of various shapes, illustrations of which accompany his report. The forms and style of decoration of these vessels are very rude; in fact it is pointed out that the decoration is much less elaborate than that found on the older pottery of the shell-heaps and pits of Yezo, and usually designated as Aino pottery. As Mr. Hitchcock remarks, it is difficult to explain the curious anomaly that the early pottery of a people who are famed at the present day for their productions in this kind of handiwork, should be inferior to the earlier productions of their predecessors, who have since absolutely lost the art of making pottery of any kind.

IT was Lœffler who most successfully exhibited in stained preparations the cilia or organs of locomotion attached to some micro-organisms. As is well known, these appendages will not stain in the usual manner, and special methods have to be adopted. Moreover, they are so delicate and easily broken or detached that the greatest care and skill have to be exercised in their demonstration. Lœffler's method consists in using a mordant, to which a certain proportion of either an acid or alkali is added, the nature as well as the proportion of the latter varying with the particular microbe under investigation. To ascertain the exact quantity required in each case is of course a very tedious process, but recent investigations have shown that the acid or alkaline reaction of the mordant may be neglected, and that equally successful specimens can be prepared when this precaution is altogether omitted. A very simple modification of Lœffler's method devised by Nicolle and Morax is published in the *Annales de l'Institut Pasteur*, July 1893, p. 554. These authors dilute a small quantity of a recent culture in water, and run a fraction of it on to cover-glasses and allow it to dry. Lœffler's fuchsin ink or mordant is then applied, heated over a small flame until it begins to steam, and then washed. This process is repeated three or four times, after which the preparation may be stained with an ordinary aqueous solution of violet and examined in the usual manner. It is stated that by thus substituting the application of the mordant three or four times for the once recommended by Lœffler, equally good results were obtained without the addition of either an acid or alkali.

AN elaborate investigation into the chemical and bacterial condition of the river Elbe at Magdeburg has been recently carried out, and the results are published in the part issued in July of the *Arbeiten a. d. Kaiserlichen Gesundheitsamte*, vol. viii. 1893. The Elbe at the intake of the Magdeburg waterworks contained on November 10, 1891, as much as 34·3 parts of chlorine per 100,000. This large proportion of chlorine sinks into insignificance when contrasted with the 130·3 parts per 100,000 present in the Saale one kilometre above its junction with the Elbe. The Saale receives the drainage from numerous potash and other works, and the waste water from one of these was found to contain as much as 656·4 parts of chlorine per 100,000, so that the brackish state of both these rivers is easily explained. Ohlmüller, who is responsible for the report, states that unless the intake of the Magdeburg water-works is removed to a more suitable spot there is every probability of the Elbe water becoming undrinkable, in spite of the exhaustive and careful filtration to which it is submitted before distribution, in consequence of its brackish taste. But another consideration also enters into the question of the desirability of this water for dietetic purposes, for the saline condition of a given water acquires a new significance since the important discovery that the cholera organism thrives luxuriantly and multiplies abundantly in water and other media containing a high percentage of salt. That the water of the Elbe remains brackish even when it reaches Hamburg was shown by chemical analyses made of this water during the cholera epidemic last year, and Percy Frankland states (*British Medical Journal*, July 29, 1893, p. 251) that he found 31·3 parts of chlorine per 100,000 in the sample which he examined. Hueppe, in his report on the Hamburg epidemic, mentions especially the salt taste which the water had. That other bacteria can also flourish in this brackish water is exhibited by the large numbers present in the Saale, there being as many as 40,440 in 1 c.c. of water abstracted about one kilometre above the point where this river joins the Elbe.

HERR A. HASEMANN suggests, in the current number of the *Zeitschrift für Instrumentenkunde*, a novel suspension for pendulums which appears to merit some further investigation. In the ordinary suspension of a knife-edge turning on a plane, a high magnification would show us a flattened cylinder working in a depression in the plane due to the elastic yielding of the material. This introduces friction and the sliding action discovered by Defforges. Herr Hasemann proposes to rest the knife-edge upon another, or rather to give both the knife-edge and its support a semi-cylindrical form. In that case the junction of the two surfaces is a plane, and for the same angle of swing the displacement of the surface of contact is much smaller. In the experiments undertaken to test this arrangement, the difficulty anticipated with regard to stability was found to be very much less than one might be led to suppose.

LORD KELVIN'S new series of electrical measuring instruments are described by Mr. Andrew Meikle in the *Electrician*. The chief representatives of this class of instruments are the recording electricity meter and the dial voltmeter. In the former, which is chiefly intended to measure the energy consumed in electric-lighting circuits, the whole current is sent through a stout coil consisting of a few turns of a copper spiral. Within this coil is suspended a vertical electromagnet made of a soft iron core wound with wire conveying a subsidiary current of $\frac{1}{10}$ ampere, which is 25 per cent. more than is sufficient for saturation. The position of this electro-magnet within the coil is recorded by an intermittent counting mechanism worked by a cam. The large dial voltmeter made for the Edison Electric Illuminating Company, of New York, depends upon the pull of a solenoid upon a suspended electromagnet as in the first instrument, but here the electromagnet is wound with 30,000 turns of fine copper wire, the current under investigation being conveyed to the coil by the spiral springs by which it is suspended. The resistance of the electromagnet coil is 1500 ohms, and the core is saturated by $\frac{1}{25}$ ampere. Electromotive forces of 60 volts and upwards are therefore measured free of residual errors. Attached to the electromagnet is a ratchet which is geared into a pinion wheel on the shaft carrying the pointer, thus giving the instrument a great resemblance with the aneroid barometer. A rod carrying two discs is screwed into the lower end of the electromagnet, and the discs, working in thick oil in a dash pot, serve to damp vibrations due to sudden changes of electromotive force. The diameter of the dial is about thirty inches.

M. D'ARSONVAL, we learn from *Électricité*, has been making experiments on the electric excitability of muscles after death, and recently sent some results of his observations to the Academy of Sciences. General opinion on this point agreed that the excitability disappeared very soon after the death of the animal, which is true only so long as one depends upon the shortening of the muscle for an indication of its sensibility. But this method is not sensitive enough to indicate disturbances of very small amplitude. For this purpose M. d'Arsonval has for many years used a special modification of the microphone, which he has named the *myophone*, and which, when it is connected with the muscle under experiment, gives a sound some time before any contraction is apparent, especially if the muscle is stretched by a spring. By this means it may be proved that nervous excitability may last for many hours after death. As an instance, the achilles tendon of a rabbit may be attached to the myophone, and the sciatic nerve excited by a current broken some 50 to 100 times per second. Besides proving that the death of a nerve is much less rapid than was hitherto supposed, these experiments also show that nerve may act on muscle without producing actual contraction, but only some simple molecular vibration.

We have received a catalogue of the library of the Akademie der Naturforscher, prepared by Dr. Oscar Grulich.

The City and Guilds of London Institute for the advancement of technical education has issued its programme of the technological examinations for the session 1893-94.

"Symons's British Rainfall" for 1892 has been published. It contains, in addition to the rainfall statistics gathered from more than three thousand observers in Great Britain and Ireland, several articles upon various branches of rainfall work.

A lecture on "Cholera Prospects and Prevention," recently delivered by Dr. Thorne Thorne, F.R.S., to the technical teachers of the National Health Society, has just been published by the Society. The teachers and the Society must benefit by putting themselves under such an excellent adviser as Dr. Thorne is upon hygienic matters.

The autumn session of popular science lectures at the Royal Victoria Hall, Waterloo Bridge-road, will open on Tuesday, September 5, with a lecture on "What I saw of New Zealand and the noble Maori," by Capt. Chas. Reade, R.N. The three other lectures of the month will be given by Prof. Malden, and will be as follows:—September 12, "Picturesque Ireland;" September 19, "Australia;" September 26, "The World's Fair and Chicago."

Three more volumes of the comprehensive Aide-Mémoire series, published by Gauthier-Villars and by Masson have been received. One, by M. Laurent Naudin, is on the manufacture of varnishes. It is divided into two parts, dealing respectively with the physical and chemical properties of the materials used, and with the actual processes involved, in varnish manufacture. M. G. Laverque is the author of a volume on turbines, which is also divided into theoretical and practical parts. The third volume is by M. A. Hébert, and deals with the means of detecting the adulteration of alcoholic drinks.

The Journal of the Marine Biological Association (vol. iii., No. 1) contains lists of the *Nemertines* of Plymouth Sound, by Mr. T. H. Riches, and the *Turbellaria* of Plymouth Sound and the neighbourhood, by Mr. F. W. Gamble. Dr. Benham contributes a paper on the post-larval stage of *Arenicola marina*, and Mr. E. W. L. Holt continues his description of the North Sea investigations carried on by him at the Marine Fisheries Society's laboratory at Cleethorpes. Mr. J. T. Cunningham contributes two interesting articles on the immature fish question, and the coloration of the skins of flat fishes.

The United States National Museum has issued in separate form the report of Dr. J. P. McMurrich on the Actiniæ collected by the U.S. Fish Commission steamer, *Albatross*, during the winter of 1887-88. The reports deals with the Edwardsiæ, Protactiniæ, Hexactiniæ, and Ceriantheæ. Dr. McMurrich will give the results of his studies of the Zoantheæ in a future report. Other recently-received excerpts from the Proceedings of the U.S. National Museum include a "Description of some Fossil Plants from the Great Falls Coal Field of Montana," by Mr. W. M. Fontaine, and a paper "On the Occurrence of the Spiny Boxfish (Genus Chilomycterus) on the Coast of California," by Prof. Carl H. Eigenmann.

An improved mode of preparing the ammonium salt of persulphuric acid, NH_4SO_4 or $(NH_4)_2S_2O_8$, is described by Dr. Elbs, of Freiburg, in the latest number of the *Journal für Praktische Chemie.* The potassium, ammonium and barium salts of persulphuric acid were obtained two years ago by Dr. Marshall, of Edinburgh, in large well-developed crystals as described in our note of Vol. 44, p. 577, and since the publication of Dr. Marshall's memoir M. Berthelot, who first pointed out the existence of the acid and its anhydride, has published an account of his further experiments upon the subject, fully confirming the results obtained by Dr. Marshall, and adding further details. M. Berthelot's latest form of electrolytical apparatus for the preparation of the persulphates by the electrolysis of solutions of the ordinary sulphates in sulphuric acid consisted of a double cell, the inner portion being constructed of porous porcelain. Into this inner porous cell of about 150 c.c. capacity was placed a concentrated solution of ammonium or potassium sulphate in dilute sulphuric acid, while the outer cell was filled with more of the dilute acid. M. Berthelot appears to have considered it essential to employ an anode of small surface in the inner cell, a piece of stout platinum wire being preferred; but a kathode of large surface was considered requisite in order to diminish the resistance of the arrangement, and a large plate of platinum was employed for this purpose. A current of three amperes was allowed to pass through the apparatus for fifteen to twenty hours, when a yield of about forty to forty-five grams of ammonium persulphate, corresponding to a yield of sixteen *per cent.* of the theoretically possible, was obtained. With the improved form of apparatus and under the conditions described by Dr. Elbs, it is possible to obtain an average yield of sixty-five *per cent.* of ammonium persulphate, the amount having even reached eighty-five *per cent.* in one experiment. As anode or positive pole a spiral of platinum wire is employed, and as kathode or negative pole a piece of sheet lead bent into a cylindrical form and surrounding the inner porous cell. The outer liquid consists of equal portions by volume of water and oil of vitriol, and the inner liquid is a saturated solution of ammonium sulphate in sulphuric acid diluted with eight times its volume of water. The apparatus is cooled during the passage of the current by a bath of pounded ice. If cold spring water is available, however, the cooling may conveniently be effected by substituting for the leaden cylinder in the outer vessel a worm of leaden tubing, through which the cold water is driven. The current of two to three amperes is only permitted to traverse the apparatus for three or four hours, when the contents of the inner cell are filtered through glass wool, which retains in the funnel the crystals of ammonium persulphate produced. The crystals are drained on porous plates, and the filtrate is again saturated with sulphate of ammonia, returned to the inner cell, and again electrolysed. There is no advantage in prolonging the experiment to twenty hours, inasmuch as the formation of persulphate occurs much more slowly after a time. After the first experiment, when a considerable quantity of ammonium persulphate remains in solution, one hundred parts of water at the ordinary temperature dissolving sixty-five parts of the salt, about forty grams of crystals are obtained in each operation of three to four hours. In order to recover the persulphate remaining dissolved after the conclusion of the preparations it is convenient to precipitate it as the potassium salt by the addition of a solution of carbonate or acetate of potassium. Potassium persulphate is much less soluble than the ammonium salt, one hundred parts of water, under the same circumstances as mentioned in the case of the latter salt, only dissolving two parts of the potassium salt. It would thus appear to be most advantageous to prepare the soluble ammonium salt as the starting-point for a study of the persulphates, and the method described by Dr. Elbs renders the operation both simple and cheap, and affords it in comparatively large quantities in a short period of time. The product may be purified from traces of admixed ordinary sulphate by first recrystallising a small portion, and subsequently washing the main quantity with the solution of the pure crystallised salt. Recrystallisation of the whole is attended with a considerable loss. The crystals are quite permanent, however, when stored in dry bottles with well-fitting stoppers.

NOTES from the Marine Biological Station, Plymouth.—Last week's captures include the Anthozoan *Gephyra Dohrnii*, the Æolid *Amphorina cœrulea*, the Cirrhipede *Scalpellum vulgare*, and the Brachyura *Ebalia tumefacta* and *Achæus Cranchii*. The floating fauna continues to be rich in trochophore larvæ of various types, as recently recorded; the larva of *Polygordius* was last week taken in addition. Among Protozoa, *Noctiluca* has become more plentiful; but the week has been especially marked by the presence of Radiolaria of several species in numbers altogether unprecedented in our experience. Other signs of an Atlantic element in the floating fauna of late are furnished by the continued abundance of the Siphonophore *Muggiæa atlantica*, both colonies, eudoxomes and larvæ, and by the capture of two specimens, sexually mature, of *Doliolum Tritonis*. The Hydroids *Aglaophenia pluma* and *myriophyllum* and the Nudibranch *Æolidiella Alderi* are now breeding.

THE additions to the Zoological Society's Gardens during the past week include a Mona Monkey (*Cercopithecus mona*) from West Africa, presented by the Misses Price; a Yellow-cheeked Lemur (*Lemur xanthromystax*) from Madagascar, presented by Miss Annie Gervers; a Bonnet Monkey (*Macacus sinicus*) from India, presented by Mr. J. W. Harris; a Short-toed Eagle (*Circaëtus gallicus*) from Morocco, and six Little Bitterns (*Ardetta minuta*) from Europe, presented by Lord Lilford; a Black-headed Gull (*Larus ridibundus*) from Brit. Isles, presented by Mrs. H. S. Wardrop; an Indian Kite (*Milvus govinda*) from Eastern Asia, presented by Mr. A. Savory; four Tortoises (——) from Formosa, presented by Mr. P. Aug. Holst; a Golden Cat (*Felis moormensis*) from Sumatra, a Slender-billed Cockatoo (*Licmetis tenuirostris*) from South Australia, and six Avocets (*Recurvirostra avocetta*) from Holland, deposited; six Avocets (*Recurvirostra avocetta*) from Holland, a Common Tern (*Sterna hirundo*) from Holland, a Japanese Ape (*Macacus speciosus*) from Japan, and a —— Hawk Eagle (*Spizaëtus* ——) from India, purchased.

OUR ASTRONOMICAL COLUMN.

THE CORDOBA DURCHMUSTERUNG.—Mr. John Thome, the Director of the National Argentine Observatory, is to be congratulated upon the publication of the Cordoba Durchmusterung Catalogue, containing the brightness and position of every fixed star down to the tenth magnitude comprised in the belt of the heavens between 22° and 32° of south declination. The results are a continuation of the Durchmusterungs of Argelander and Schönfeldt from their southern limit. In the present volume 179,800 stars are catalogued, but altogether the places of 340,380 stars have been determined down to − 42°. The observations for this great catalogue were begun in 1885 and ended early in 1891. They reach the enormous number of 1,108,600, and were made entirely by Mr. Thome and Mr. R. H. Tucker. The area over which the observations have extended is 6075 degrees of a great circle, hence the mean density of stars is 56·2 stars per square degree. The corresponding mean density for Argelander is 15·2, and for Schönfeldt 18·5. The density varies considerably, however, in different parts of the sky, and ranges from 70 to 160 stars per square degree in the Milky Way. Mr. Thome says that a series of twelve maps, each embracing two hours of right ascension and twenty degrees in declination, has been constructed upon the scale adopted by Argelander, and will be issued during next year with the second volume of the catalogue, containing stars within the belt from 32° to 42° south declination. The construction of these maps, and the preparation of a catalogue like that of which the first part has just reached us, involves an enormous amount of labour. Indeed, it is difficult to understand how, amidst the vicissitudes to which an observatory in the Argentine Republic must be subject, and with such a meagre staff as that under Mr. Thome's direction, it has been possible to do so much excellent work.

THE RORDAME-QUÉNISSET COMET.—On July 11 the Rordame-Quénisset comet (*b* 1893) was photographed at Goodsell Observatory, and a fine photogravure reproduction of one of the views forms the frontispiece to the August number of *Astronomy and Astro-Physics*. In a letter that appears in the same journal, Prof. J. E. Keeler describes the spectroscopic observations of the comet made at Allegharry Observatory. On July 10 the three usual carbon bands were seen, connected by a narrow continuous spectrum from the nucleus. Each band appeared to terminate sharply on its less refrangible side, where also the brightness was greatest. No direct comparison of spectra could then be made, so the positions of the bands were estimated. A photograph of the comet spectrum in juxtaposition with the solar spectrum obtained from the moon was procured on July 19. Upon the photograph could be seen a hazy band at λ 472 and another terminated by a line on the less refrangible side at λ 388, and fading away towards the more refrangible end of the spectrum. Between these two bands others were suspected, but could not be made out with sufficient accuracy for a determination of wave-length. A comparison of the spectrum of the comet with that of a spirit lamp on July 20 showed that the bands were coincident in the two spectra. The brightest comet band—that in the green—appeared to have a second maximum coincident with the second maximum of the corresponding carbon fluting

A SIMPLE EQUATORIAL MOUNTING.—M. J. Jarson describes in *L'Astronomie* for August a simple, if not new, means by which small telescopes can be moved equatorially, thus permitting an observer to keep objects in the field of view without constantly moving the telescope in altitude and azimuth. Applying this method, for instance, to a small telescope mounted on a small vertical tube, tripod fashion, such as those generally used at seaside resorts, the following account may show the simplicity of the arrangement. On the stand of the telescope a bar of wood or of iron is fixed horizontally, in which is a hole sufficiently large to pass a cord. The position of the hole is determined by the rule that the line joining the centre of motion of the telescope in declination to this hole makes an angle with the horizontal bar equal to the latitude of the place of observation. By connecting the object-glass end of the telescope to this hole, by means of a chain or cord, any celestial object can be followed in the heavens by simply keeping the cord tight and moving the telescope. A weight fastened to the eye end secures the tightness of the cord. The telescope will then describe an arc of a circle in the heavens, and not a straight line as formerly. For different objects it is obvious that one must vary the length of the cord; but for making prolonged studies of any particular one possessors of small instruments will find this a most useful arrangement.

A REMARKABLE SOURCE OF ERROR.—Dr. E. Von Rebeur-Paschwitz, in No. 3177 of the *Astronomische Nachrichten*, publishes some interesting curves traced by a horizontal pendulum during the prevalence of certain slight earth tremors occurring on different occasions and at different places. Traced photographically on sensitive plates moving with a velocity of twenty-four inches per minute, these tremors show a striking similarity to those observed by Prof. Milne in Japan. It appears that the surface of the earth is occasionally subjected to wave motions analogous to those disturbing a sheet of water, and often persisting with great regularity for several hours. Their connection with steep barometric gradients is probable, although that does not appear to be the only condition. In any case, the tremors appear in the presence of strong winds, at least in the neighbouring country, and they travel with at least the velocity of 2 km. per second. The influence of these tremors upon observations of polar distances, and upon spectro-photographic work, is sufficiently obvious to render it desirable that all observatories should be fitted with automatic instruments for registering these disturbances, and arrangements should be made for their study and comparison.

THE APEX OF THE SUN'S WAY.—In a letter to the editor of the *Bulletin Astronomique*, Prof. H. G. van de Sande Bakhuyzen says that he has determined the apex of the movement of our system from all Bradley's stars of which the distances from the pole of the Milky Way are less than 50°. In the calculation, he made use of the method employed by L. Struve in his memoir on the determination of the movement of the solar system, in order that the two results might be strictly comparable. Prof. Bakhuyzen has also repeated the calculations, using stars in the same part of the heavens as the above, but with proper motions not exceeding 0″·075. The first method gave, as the position of the apex,

R.A. = 264°, Decl. = 30°.

The result obtained by the second calculation was—

R.A. = 290°, Decl. = 24°.

The position found by L. Struve was—

R.A. = 273°·3, Decl. = 27°·3.

Prof. Bakhuyzen is at present occupied in determining the apex from stars of small proper motion in the Milky Way.

THE ORIGIN OF NEW STARS.—In the current number of *Die Natur* Prof. G. Hoffmann surveys the various new stars discovered since Tycho Brahe's Nova Cassiopeiæ, and the different theories advanced to account for their appearance. He is inclined to endorse the views of Prof. Seeliger, according to which the sudden brightness is produced by a heavenly body entering a "cosmic cloud" consisting of sparsely distributed matter. Prof. Hoffmann thinks that all new stars may be regarded as essentially of the same type as the variables of long period.

THE MINUTE STRUCTURE OF PLANT HYBRIDS.[1]

DR. MACFARLANE'S paper will not fail to impress biologists by the suggestiveness of some of his speculations and with the importance of his observations. Nor are his conclusions limited to the plant hybrids, which he discusses, but they apply, though with certain limitations, to all organisms resulting from sexual reproduction.

Of course, in the case of hybrids, the parental characters are often very different, and can therefore be easily recognised in the offspring, whence the examination of their characters, including, of course, their minute anatomy, becomes important to all who are interested in the problems of reproduction. For in the case of fusion of reproductive cells of the same species, where the parental characters differ often very slightly, it is difficult, and at times impossible, to distinguish whether the characteristics of the male or female parent predominate, or whether a complete blending has taken place. Theoretically perhaps we should expect this blending of characters, but our everyday experience brings to our mind so many instances of almost unadulterated inheritance of paternal or maternal characteristics, that we are somewhat prejudiced against a conclusion to which Dr. Macfarlane's observations on hybrids lead him, and which ought equally to apply to normal offspring.

The study no doubt presents many difficulties, which are, it is true, recognised by the author, but do not seem to him insuperable. First and foremost we have the variability of what are usually termed true species; and the author is careful to point out that "for hybrid investigation one should be acquainted with the parent individuals and the conditions under which they were grown, or try to choose an average specimen for study." But in either case errors may creep in. For if one of the parents has varied abnormally, though some of the offspring will inherit such a variation, others may revert to the more normal condition of their grandparents or great-grandparents. If, on the other hand, we choose the average specimen, we are entirely in the dark as to any special variation of the parental form. Nothing short of selecting normal individuals as parents and examining all or a large number of the hybrid offspring would afford sufficient basis for such conclusions, as the author deduces from his less complete observations. But Dr. Macfarlane does not even state in each case whether his observations are taken from the parents themselves, or only from average specimens.

The conditions of growth, too, enormously affect some of the characters which the author has chosen for comparison. The character of leaves for instance, especially as regards their tran[s]piratory functions, can be completely altered by the treatme[nt] of the young plant. If, therefore, the number of stomata p[er] unit of surface are to be of any value for comparison of form[s] both the parents and the offspring must be raised under simil[ar] conditions. If this is not the case we should expect the of[f]spring to resemble in this particular that parent which w[as] grown under conditions most similar to itself. Nor does th[e] author fail to find such a case. *Hedychium Sadlerianum* ap[]proaches very nearly in the number of stomata on the low[er] surface the condition of one of its parents, *H. coronarium*; bu[t] we are told nothing as to the condition under which the paren[ts] or offspring were reared, and the tendency to "sway toward[s] one parent" is explained by the assumption that it is "[a] morphological adaptation in the hybrid for physiological work[,] or in the truest sense a case of physiological selection."

Having thus briefly stated some of the difficulties besettin[g] the problem, we may state that all his observations and measure[]ments, down to the size of the plastids and starch grains, lea[d] the author to the conclusion that plant hybrids, at least se[ed] hybrids, are, both in their minute structure and in their genera[l] life-phenomena, intermediate between their parents.

This complete blending is, to say the least, very extra[]ordinary, and we are tempted to question whether the autho[r] has investigated a sufficient number of individuals of eac[h] hybrid. Surely the variability of hybrids would be sufficient to supply any investigator with numerous examples which wer[e] not intermediate. The unanimity of the observations publishe[d] make it imperative that some further investigations should b[e] undertaken with regard to the variability of hybrids, a facto[r] to which sufficient prominence is not given in the presen[t] paper.

Darwin insists both in his "Forms of Flowers" and al[so] in his "Cross and Self-fertilisation of Plants," upon th[e] correspondence between the crossing of distinct species an[d] legitimate unions of dimorphic and trimorphic heterostyle[d] plants. Yet from Dr. Macfarlane's paper we must conclude tha[t] in some respects at least there is no correspondence.

For Darwin states that though "the shape of the stigma an[d] the length of pistil both vary, especially in the short styled form[,] I have never met with any transitional states between the tw[o] forms in plants growing in a state of nature." Now the differ[]ence in these forms extends also to anatomical details, such a[s] the size of the pollen-grain and the size of the stigmatic hairs[,] and yet the offspring will all resemble either one or the othe[r] parent, and thus differ radically from all the hybrids which Dr[.] Macfarlane has examined, all of which represent forms inter[]mediate between the two parents. Dr. Macfarlane has of cours[e] come across some exceptions, but we are not told whether they are merely individual variations approaching one or other of the parents, such as we should expect to find, or whether in th[e] production of the hybrid there was always a tendency to approxi[]mate the male or female form. Whichever be the case, th[e] author is of the opinion that the number previously asserted to diverge towards one of the parents has been considerably over-estimated.

The author's contribution, however, to the investigation and discussion of graft hybrids is extremely valuable, and we cannot help wishing that he had found more similarity in the characters of graft and seed hybrids. We feel convinced, though we should not like to impugn the evidence brought forward, tha[t] the latter does not represent the average condition of the struc[]ture of plant hybrids, but that there must be more variation in their characters than the author has found in the specimens he was enabled to examine, especially more variation towards one or other of the parent forms, though we should not expect it to be so pronounced as in the case of graft hybrids. F. E. W.

COMPULSORY LAWS OF ERROR IN DRAWING.

Digest of the Phenomena, with Examples.

THE object of the following paper is to present the facts in the briefest and, it is hoped, the plainest possible manner, for the purpose of calling attention to phenomena connected with the art of drawing, or depicting form in outline. It is to prove that error made in such drawing comes under the dominion o[f] natural law, or compulsion, and is not the result of individua[l] misconception of truth. The phenomena are altogether distinc[t] from intellectual aptitude, the intelligent and the dull being equally liable to commit the errors in the forms which will hereafter be specified.

Consideration will first be given to the existence of *general laws*, of which there appear to be three, so strongly marked as to stand clearly distinguishable as including in themselves the minor manifestations. These laws are as follows:—

(1) There is a general law making us fundamentally incapable of drawing in perspective. It is a radical condition—not of ignorance of the laws of perspective but of active negation of them. It is a natural necessity to show by the arrangement of lines the exact contrary to true perspective. It is persistent, and exists long after correct knowledge of the true arrangement of the lines is acquired, and the error is always liable to appear on any occasion of forgetfulness—that is to say, when drawing is not done with the true principles immediately in remembrance in the mind. It is perceivable in the form of direct *divergence* of lines (parallel in nature) which in perspective should *converge* to their vanishing point.

(2) Another general law is a natural incapacity to erect a proper perpendicular for an object unless the same occurs close on the line of direct sight (forward). If the perpendicular be situate laterally, and especially if it be short, it is liable to a deflection. This deflection occurs in the following manner:—If the same be on the right hand the line inclines from its top towards the central line of sight (forward); its foot is therefore nearer this central line than its top. On the left hand the phenomena are directly reversed. This error occurs whether the perpendicular be the obvious physical corner line of a solid or whether it be the integral (invisible) line of any such solid or of a drawn figure.

(3) The next general law is less distinct, but still abundantly provable on test. It affects those lines which, being in right angles to the observer, lie laterally to him; that is to say, if a line of the surface (horizontal) of a figure occur on the right or left hand, at a little distance, the line is not drawn with perspective inclination to the *vanishing point* in front of the observer, but is *drawn as a perpendicular*, or, as is evident, in such a manner as would be the true fact of its direction, void of the influence of perspective. Thus, if a square lie two or three feet to right or left of the draughtsman, those two sides of it which are the sides rectilinear, not sides parallel to the base of the picture-plane, are drawn as two perpendiculars, while they should be converging lines towards a point which leads them diagonal-wise across the paper.

These brief particulars are intended to give an account of the primary, or general, laws. All other manifestations are deducible from them—that is, in every case where a special aspect of a figure draws out its special error, this is seen to have its origin in one or other of these three primary laws. From this point I now proceed to illustrate with examples selected from three figures—the cube, the pyramid, and the hexagon—instances of special error. Other geometrical figures may at a future period be likewise illustrated, but the intention is in this paper only to broach the subject.

The Cube.

It is in all cases assumed the object lies on a table before the observer.

Position 1.—Let the cube be placed on the right or left, and with two planes parallel to the picture-plane, two in right angles.

Error 1.—The perpendiculars will be inclined as radiants upwardly.

Error 2.—The 3 perspectives visible will diverge.

Error 3.—Or these will be neutralised of perspective, and the true perpendiculars be inclined.

Position 2.—Let the cube be situate anglewise on the direct line of sight.

Error 1.—All 6 perspectives to right and left diverge.

Error 2.—Or the top is drawn as a *square*.

Position 3.—Poise the cube on an edge, so that one plane, resting exactly balanced on its corner, is in the direct front, and parallel to picture-plane.

Error 1.—The perspectives (3) will diverge.

Error 2.—The square of the front plane will be confused as rhomboidal.

Position 4.—Still having the cube poised on an edge, let it be turned so that three faces are seen at one time, and it presents perspectives in 9 lines.

Error 1.—All the perspectives, in groups of 3 each, for each plane, will diverge.

The Pyramid (Square).

Position 1.—Let the pyramid lie exactly in front, parallel to the picture-plane.

Error 1.—The two parallel edges of the square base, extending in right angles from the eye, will diverge.

Error 2.—The further side of the pyramid will thus be longer than the nearer side.

Position 2.—Let the pyramid lie on the same spot, but with an angle presented, so that the sides of the square extend in equal angles.

Error 1.—If the view of it should be isometrical, or the pyramid *flattish*, the perspectives will be shown diverging.

Position 3.—Place the pyramid point downwards towards the observer, in front, and with one side for a base.

Error 1.—The two parallel retiring lines of the inclined *real base* will show divergence.

Error 2.—Consequently, the further line of base will be longer than the nearer and upper of this sloping square.

Position 4.—Place the pyramid so that it still lies on a side for a base, but in front, and the apex and the central point of a side of the real base are on a line parallel to picture-plane.

Error 1.—The apex, which should thus lie horizontally *even* with the central point of that line of real base, which touches the ground, will be shown *below* that line. The true relation to central point given is never seen.

Error 2.—Such perspectives as occur will diverge.

The Hexagon.

Position 1.—Place a solid hexagon upright in the exact front of observer, with two planes parallel to picture-plane.

Error 1.—All perspectives of the parallel sides will diverge.

Error 2.—Consequently, the two parallel lines (integral) which connect opposite angles of the hexagon will lose *their* perspective.

Position 2.—Place the hexagon on a side, so that its lines, then horizontal, are parallel to picture-plane and the object is in a lateral situation, or not in front.

Error 1. The end, which is now a plane in right angles, will show the integral connecting lines between top and bottom angles *leaning*, because these are essentially perpendicular; therefore the perpendicularity is distorted. (General law 1.)

Error 2.—The line (integral) connecting the two angles midway between top and base line of this plane, and which should be of course *parallel* to these, and partaking of their perspective, will have a course diagonal to them, always deflected downwards.

Error 3.—The lines which indicate the further, or unseen plane of hexagon will show exact conformity to this error; also diverging perspective.

Position 4.—Place the hexagon again laterally, with its end as a front plane, and a side on the ground, the direction of the object being in a due rectilinear line.

Error 1.—The perspective bias will be lost (general law 3) and the lines traced as perpendiculars.

Error 2.—Or these will indicate divergence in place of convergence.

Error 3.—The plane parallel to picture-plane, and essentially void of distortion, will be nevertheless distorted.

Position 3.—Place the hexagon, still resting on a side, so that its lines take a diagonal line with regard to a line parallel to the picture-plane, and it must be in front.

Error 1.—The displacement of the integral perpendiculars will occur in the end planes, as in Error 1 of Position 2.

Error 2.—The Error 2, in Position 2, will be repeated.

Error 3.—The perspectives will diverge.

ARTHUR L. HADDON.

THE DEPARTMENT OF SCIENCE AND ART.

THE fortieth Report of the Department of Science and Art has just been issued, and is of a highly satisfactory character. From it we learn that in 1892 there was a very large increase, not only in the number of students and classes, but also in the number of schools or separate institutions in which science is taught. The number of classes in different branches of science in 1892 was 10,352, as against 8,568 in the preceding year, and the number of pupils under instruction showed the remarkable increase of 32,002, the totals for 1891 and 1892 being respectively 148,408 and 180,410. The number of examination papers worked was 203,347, and the number of individual examinees 108,858, so there was an average of nearly two papers for each student. The greatest number of papers, 29,051, was worked in mathematics. In physiography, 21,944 papers were written, and in theoretical inorganic chemistry, 21,578 papers. The lowest number of candidates were presented in mineralogy and nautical astronomy, the number of papers worked in these subjects being 119 and 141 respectively. With regard to the extent to which local authorities are devoting funds for the purposes of science, art, technical, and manual instruction, it is reported that "Of the forty-nine councils of counties in England (excepting Monmouth), forty-two are now giving the whole of the residue to technical education, while the remaining seven are giving a part of the amount; and of the sixty-one councils of county boroughs, fifty are devoting the whole of the residue to the same purpose, and ten are devoting a part of it, no decision having yet been arrived at in the case of Great Grimsby (which it may be mentioned was only constituted a county borough on April 1, 1891). Of the councils of the sixteen counties and county boroughs of Wales and Monmouth, to which the Welsh Intermediate Education Act, 1889, applies, fifteen are applying the whole of the residue to the purposes of intermediate and technical education, and one a part of it. Contributions are also made out of the rates under the Technical Instruction Act, 1889, in the case of seven counties and county boroughs in Wales and Monmouth. As regards Scotland, so far as returns have been received, the whole of the residue fund is being applied to technical education in the case of twenty counties (out of thirty-three) and sixteen burghs and police burghs (out of 187), while six counties and thirty-nine burghs and police burghs are giving part of it to the same purpose. Of the remainder, the majority of the local authorities are devoting the residue to the relief of rates, and a small proportion of them have under consideration the question of applying the money to technical education."

In conclusion, it is pointed out that "the opportunities afforded to people engaged in all branches of industry for acquiring a knowledge of much which is closely connected with their daily work, but which cannot be obtained in the factory or workshop, are constantly increasing. The municipal schools, which are steadily growing in number and efficiency in all parts of the country, must be of great service in this connection. Further, in proportion as local interest is developed, and employers show that they value sound scientific instruction and art teaching, the effectiveness of these schools will be promoted But whether the income of these schools be derived mainly from local or Imperial sources, it is essential that the course of instruction adopted shall be well adapted to the needs of the town or district. The more fully the educational welfare of the students takes the first place, and the mere earning of Government grants the second place in the new Municipal schools, the more certainly will they fulfil their object."

It is clear from this that the Department desires to stamp out the system whereby science classes are "farmed" by teachers. The acquisition of knowledge is rightly regarded as the proper goal, not the mere obtaining of a certificate. The technical instruction committees of some of the county councils would do well to bear this and the following admonition in mind: "Without a sound foundation of general education, the highest scientific training cannot be imparted; without a sufficient supply of teachers with adequate salaries, who are not overworked, and who not merely know their subject, but know how to teach it, a considerable part of the money expended on the encouragement of new forms of education must be wasted."

EUROPEAN LABORATORIES OF MARINE BIOLOGY.

MARINE laboratories are now recognised as essential to the progress of biology. The facilities they offer the collector and the investigator cannot be overrated, and it would be an excellent thing if institutions could be conducted on similar lines in every branch of science. Mr. Bashford Dean, in the *American Naturalist* of July, gives an illustrated description of marine laboratories in Europe, which is so interesting that a large portion of it is here reprinted. The description of the Marine Biological Station at Plymouth is omitted owing to the fact that a detailed account has already appeared in these columns (vol. xxxviii. p. 198, 1888). Mr. Dean prefaces his report as follows:—

"In every country the marine laboratory has become a need of the student of biology. During his winter studies in the university it serves to provide him with well-preserved material, often with living forms which he may himself prepare according to his wants; in summer it gives him opportunity to see and collect his study types, and utilise with profit and without physical discomfort abundant material relating to his studies. To the investigator the marine laboratory has become, in the broadest sense, a university. He may there meet the representative students of far and wide, fellow-workers, perhaps, in the very line of his own research, and must himself, unknowingly, teach and learn. He finds out gradually of recent work, of technical methods which often happen most pertinent to his present needs. He may carry on his work quietly and thoroughly; his works of reference are at hand; he has the most necessary comfort in working—the feeling of physical rest, untroubled by the rigid hours of demonstrations and lectures.

"The importance of the work of the marine laboratory has been keenly appreciated in foreign countries, and it is noteworthy how large a number of the original researches is at present conducted at, or upon material from, these distributing centres of biology. At the present day the entire coast line of Europe has become dotted with zoological stations great and small, grown out of the resources granted by societies, private individuals, or governments—perhaps by the combined efforts of all. It is a matter of great interest to note how thoroughly the marine laboratory system abroad had become a part of every grade of biological work. The student in a small university in the interior of France receives his first lessons from material sent regularly from Roscoff or Banyuls. He examines *living* sponges, hydroids, lucernarians, pennatulids, beroës, *Loxosoma*, *Comatula*, and *Amphioxus*. In Munich, hundreds of miles from the sea, is another example. Prof. Richard Hertwig, by the aid of material from Naples, demonstrates the larval character of ascidians, or the fertilisation of the egg of the sea urchin. Every group of European universities seems to have centralised its marine biological work in a convenient locality, and this branch of their needs is supported—and is well supported—even in countries whose financial resources are most limited. The importance of this work is felt to such a degree that it is not from reasons unselfish that universities have united in their support of a station like that of Naples. This has become literally an emporium cosmopolitan, bringing together side by side, perhaps not unnaturally, the best workers of many universities whose observations upon the best material, sharpened by discussion and criticism, are certainly tending to become the most accurate and the most fruitful in their direction and results.

"It is most singular that foreign countries are unquestioningly liberal in the support of *pure* biology, and in the work of marine stations the tendency is becoming less and less on the part of money-givers to ask how many fish will be hatched to become food material. Public interest has been gradually coming to be directed to the general laws and the problems of life and heredity. This has well been a hopeful sign, and the European biologists are not backward in emphasising the importance of their studies. Prof. de Lacaze-Duthiers does not hesitate even to propitiate the practical Cerberus, reminding him how often 'facts have been found at every step of science which were valueless at their discovery, but which, little by little, fell into line and led to applications of the highest importance—how the observation of the tarnishing of silver, or the twitching leg of the frog, was the origin of photography and telegraphy—how the purely abstract problem of spontaneous generation gave rise to the antiseptics of surgery.'"

Beginning with the marine laboratories of France, Mr. Dean says:—

"The extended sea-coast has ever been of the greatest aid to the French student—along the entire northern coast the channel is not unlike the Bay of Fundy in the way it sweeps the waters out at the lunar tides. The rocks on the coast of Brittany, massive boulders, swept and rounded by the rushing waters, will, at these times become exposed to a depth as great as 40 feet. This is the harvest-time of the collector; he is enabled to secure the animals of the deep with his own hand, to take them carefully from the rocky crevices where they would ever have avoided the collecting dredge. From earliest times this region has been the field of the naturalist. It was here that Cuvier, during the Reign of Terror, made his studies on marine invertebrates which were to precede his "Règne Animal." The extreme westernmost promontories of Brittany have, for the last half-century, been the summer homes of Quatrefages, Coste, Audouin, Milne-Edwards, and de Lacaze-Duthiers. Coste created a laboratory at Concarneau, but this has come to be devoted to practical fish culture, and is, at the present day, of little scientific interest. It is owing to the exertions of Prof. de Lacaze-Duthiers of the Sorbonne, that the two government stations of biology have since been founded. The first was established at Roscoff, in one of the most attractive and favourable collecting regions in Brittany, and has continued to grow in importance for the last twenty years. As this station, however, could be serviceable during summer only, it gave rise to a smaller dependency of the Sorbonne in the southernmost part of France, on the Mediterranean, at Banyuls, which had the additional advantage of a Mediterranean fauna.

"To these French stations should be added that of Prof. Giard, at Wimereaux near Boulogne, in the rich collecting funnel of the Straits of Dover; that of Prof. Sabatier at Cette, not far from Banyuls, a dependency of the University of Montpelier; that of Marseilles, and the Russian station at Ville-Franche, near the Italian frontier. An interesting station in addition, is that at Arcachon near Bordeaux, founded by a local scientific society, and having at its command the collecting resources of a small inland sea, famous for its oyster culture. Smaller stations are not wanting, as at the Sables d'Olonne.

"At Roscoff the laboratory building looks directly out upon the channel. In its main room on the ground floor, work-places are partitioned off for a dozen investigators; this on the one hand leads to a large glass-walled aquarium-room, while on the other opens directly to adjoining buildings which include lodging quarters, a well-furnished library, and a laboratory for elementary students. Surrounding the building is an attractive garden, which gives one anything but a just idea of the barrenness of the soil of Brittany. From the sea-wall of the laboratory one looks out over the rocks that are becoming exposed by the receding tide. A strong enclosure of masonry serves as a *vivier* to be used for experiments as well as to retain water for supplying the laboratory. The students are, in the main, those of the Sorbonne, and are under the direction of Dr. Prouho, their *maitre de conférences.* They are given every opportunity to take part in the collecting excursions, frequently made in the laboratory's small sailing vessels, among the rocky islands of the neighbouring coast. Strangers, too, are not infrequent and are generously granted every privilege of the French student. Liberality is one of the characteristic features of Roscoff. The stranger who writes to Prof. de Lacaze-Duthiers is accorded a work-place which entitles him gratuitously to every privilege of the laboratory—his microscope, his reagents, even his lodging-room should a place be vacant. It seems, in fact, to be a point of pride with Prof. Lacaze that the stranger shall be welcomed to Roscoff, and upon entering the laboratory for the first time, feel as much at home as if he had been there a week. He finds his table in order, his misroscope awaiting him, and the material for which he had written displayed in stately array in the glass jars and dishes of his work-place. So, too, he may have been assigned one of the large aquaria in the glass aquarium room—massive stone-base stands, aërated by a constant jet of sea water. He finds a surprising wealth of material at Roscoff, and his wants are plentifully and promptly supplied.

"At Banyuls, the second station of the Sorbonne, the buildings are less imposing than those of Roscoff. It is a plain, three-storey building facing the north, at the edge of the promontory which shelters the harbour of Banyuls. The vivier is in front of the station, behind is a reservoir cut in the solid rock—receiving the water of the Mediterranean, and distributing it throughout the building. On the first floor is a large aquarium-room lighted by electricity, well supplied with tanks, and decorated with statuary given by the Administration of the Beaux-Arts. The bust of Arago occupies an important place, as the laboratory has been named in his honour. The wealth of living forms in the aquaria shows at once by variety of bright colours the richness of southern fauna. Sea lillies are in profusion, and are gathered at the very steps of the laboratory. The work-rooms of the students are on the second floor, equipped in a manner similar to those of Roscoff. The director of this station is Dr. Fréderic Guitel. It is usual during the holidays at fall or winter, for the entire classes of the Sorbonne to spend several days in collecting trips in the neighbourhood. The region, with its little port, is famous for its fisheries, and one in especial is that of the Angler, *Lophius.*

"The station on the Straits of Dover, at Wimereaux, has earned a European reputation in the work of Prof. Giard. It is but a small frame building, scarcely large enough to include the advanced students selected from the Sorbonne. The laboratory is, in a way, a rival of Roscoff, and it is noteworthy that its workers seem to make a point of studying the laboratory methods of the German universities.

"The marine laboratory of Arcachon, one of the oldest of France, was built in 1867 by the local scientific society, and was carried on independently until the time of the losses of the Franco-Prussian War. Its management was then fused with that of the faculty of medicine of Bordeaux, with whose assistance, aided by that of a small subsidy from the government, the work of the institution is carried on. Arcachon, in itself, is a most interesting locality near Bordeaux. It has become a summering-place, noted for its pine-lands and the broad, sandy *plage,* picturesque in summer with swarms of quaintly-dressed children, the local head-dress of the peasant mingling with the latest toilets from Paris. Here and there is to be seen that accompaniment of every French watering-place, the goat boy in smock and berret, fluting to his dozen charges who walk in a stately way before him. The Bay of Arcachon is a small, tranquil, inland sea, long known for its rich fauna. In large part it is laid out in oyster parks which constitute to no small degree the source of wealth of the entire region. Shallow and warm waters seem to give the marine life the best conditions for growth and development. The laboratory is placed just at the margin of the water. It includes a dozen or more work-places for investigators, well supplied with aquaria, a library on the second floor, a small museum containing collections of local fauna, including the numerous relics of Cetaceans that have found their way into this inland sea. A small aquarium-room, opened to the public, is well provided with local forms of fishes, and like that of Naples, is eagerly visited. Those who are entitled freely to the use of the work-places are instructors in French colleges, members of the Society, and all the advanced students from the colleges of the State. For other students work-place is given upon the payment of a fee whose amount is regulated each year by the trustees. As at Roscoff, material is plentifully supplied.

"The zoological station at Cette is a direct annex of the University of Montpelier. The present temporary building is to be replaced by one of stone, which will enable Prof. Sabatier to add in no little way to the working facilities of his students. The region, in every essential regard, is similar to that of Banyuls.

"The station at Marseilles is devoted in great part to questions relating to the Mediterranean fisheries, and owes, in a measure, its financial support to this practical work.

"The station at Ville-Franche is essentially Russian. An account of this with figures has recently been published (Russian text) in Cracow. The station itself is well known through the work of Dr. Bolles Lee, and it is here that Prof. Carl Vogt has been a constant visitor."

After a description of the Plymouth laboratory, Mr. Dean mentions those of Liverpool and St. Andrews, north-east of Edinburgh concerning which he remarks: "The work of these stations is only in part purely biological; the practical matters of fisheries must be considered to insure financial support. In addition to these there are several stations, notably one south-east of Edinburgh, and another, recently equipped, on the Isle of Man.

"At St. Andrews, Prof. MacIntosh has studied the questions relating to the hatching and development of the North Sea fishes. Its situation upon the promontory leading into the Firth of Forth seems to have been especially favourable for the study of the North Sea fauna—the locality, moreover, is far enough northward to include a number of boreal forms. The importance of St. Andrews is at length better recognised, and a substantial grant from the Government will enable a large and permanent marine station to be here constructed. The facilities for work have, up to the present time, been somewhat primitive—a simple wooden building, single-storied, has been partitioned off into small rooms, a general laboratory, with work-places for half a dozen investigators, a director's room, aquarium, and a small outlying engine house with storage tanks. The laboratory owns a small sail-boat to assist in the work of collecting."

Passing to Holland, we read—"Holland, in the summer of 1890, opened its zoological station in the Helder, a locality which, for this purpose, had long been looked upon with the greatest favour. There is here an old town at the mouth of the Zuyder Zee, the naval stronghold of Holland, a station favourable for biological work on account of the rapid running current which renews the waters of the Zee. The station was founded by the support of the Zoological Society of the Netherlands, whose valuable work by the contributions of Hubrecht, Hoek, and Horst has long been known in connection with the development of the oyster industry of Holland. The work of the society had formerly been carried on by means of a portable zoological station which the investigators caused to be transplanted to different points along the East Schelde, favourable on account of their nearness to the supplies of spawning oysters. The present station at the Helder is situated directly adjoining the great Dyke, a small stone building of two storeys, surrounded by a small park. In itself the laboratory is a model one—the rooms are carefully finished and every arrangement has been made to secure working conveniences. A large vestibule leads directly into two laboratory rooms, and by a hallway communicates with the large, well-lighted library, and the rooms of the director. The aquarium-room has, for convenience, been placed in a small adjacent building. The director of this station is Prof. Hoek, and the president of the society is Prof. Hubrecht."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE Stanford University of California (the *Times* says) is rapidly becoming the wealthiest institution of the kind in the world. Yet there are several American Universities and colleges which enjoy enormous wealth. For example, Columbia University has an invested capital of £2,600,000; Harvard, £2,200,000; Yale, £2,000,000; the California, £1,400,000; and the Johns Hopkins, £600,000. The endowment fund of the Stanford University cannot at present be stated, partly because the benefaction exists in the shape of property which is rapidly increasing in value. But estimates which appear to be well founded have been made at San Francisco showing that at no distant date the University will be worth £40,000,000, yielding an annual income of £2,200,000.

SCIENTIFIC SERIALS.

Wiedemann's Annalen der Physik und Chemie, No. 8 (1893).—Polarisation of undiffracted infra-red radiation by metal wire gratings, by H. E. J. G. du Bois and H. Rubens. Polarised light passing without diffraction through silver wire gratings experiences in general a rotation of its plane of polarisation. The transmitting power of the gratings for light polarised in a plane perpendicular to the length of the wires was found to be greater than that for light polarised in a plane parallel to them. The present experiments were conducted with finer gratings than before the smallest interval attained being 0·001 cm. and the measurements were taken in the infra-red region. The intensity of radiation transmitted was measured by the bolometer. It was found that as long as the wave length does not exceed a certain value, the grating transmits a larger fraction of the radiation when the electric vector is parallel to the wires; this value appears to be independent of the width of interval, but characteristic of the metal; for greater wave-lengths the transmittance is greater when the magnetic vector lies in the direction of the wires.—The superior limit of wave-lengths which may occur in the thermal radiation of solids; a conclusion from the second law of thermodynamics, by Willy Wien. Assuming the second law, and the existence of none but Maxwell's ponderomotor forces in the pressure exerted by a gas, the author shows that thermal radiation does not imply waves of all lengths, but that the curve of energy, when traced along the spectrum, falls continuously to infinitesimal values on the less refrangible side, and practically disappears in the region of Hertz's finite waves.—Electric oscillations of molecular structures, by H. Ebert. It is shown that the mechanism of luminescence may be fully explained by Maxwell's theory, regarding the luminous molecules as analogous to Hertz oscillators of very small dimensions.—A photometer, by E. W. Lehmann. This is constructed on the principle of Joly's photometer; it consists of two totally reflecting prisms placed side by side in a box. In each prism one of the adjoining faces is ground, and the two ground faces are turned in opposite directions so as to be illuminated by the two sources to be compared. The plain faces are turned towards the observer, with their edges touching. The observer looks at them through a tube containing a telescope; the box to which the tube is attached can be swung round through 180°, so as to exchange the ground faces. The sensitiveness is such that forty successive readings with amyl acetate burners at 120 cm. gave results not differing by more than 0·4 per cent.

Bulletin de l'Académie de Belgique, No. 6 (1893).—We notice the following among the scientific papers: Megamicros, or the sensible effects of a proportional reduction of the dimensions of the universe, by J. Delbœuf. According to Laplace, if the dimensions of all the bodies in the universe, their mutual distances and velocities were to increase or diminish in a constant proportion, these bodies would describe the same curves as they do now. The appearances presented to observers would be the same, and independent of the dimensions assumed. Hence the only facts we are able to appreciate are ratios. In opposition to this theorem, M. Delbœuf shows that if a system consisting of the sun and the earth were to be diminished in linear dimensions to one-half, all densities remaining the same at homologous points, and the orbital velocity of the earth were reduced to one-half its value, there would be certain changes in the relations of an observer to his surroundings which could not escape notice. The velocity of sound propagation will be the same as before, but the distance traversed during a certain number of vibrations will appear larger. If a metric system were to be determined on the reduced planet in a manner analogous to ours, the hectare will be a quarter, the litre one-eighth, and the kilogramme—owing to the reduction of gravitation—one-sixteenth of the corresponding actual measures. Hence the work done in lifting a kilogramme through one metre will be $\frac{1}{32}$ of an actual kilogramme-metre. Muscular power, on the other hand, being proportional to the volume or mass of muscle, will be only reduced to one-eighth, and the observer will be able to lift four times the previous maximum weight. All work necessary for life will proceed at four times the usual rate, and hence life itself will be more rapid. These considerations pursued by the author into the regions of building, thermometry, animal heat, respiration and circulation, go to show that real space is different from geometric space, and that the dimensions of the universe are absolute.—Note on the variations of temperatures of transformation below and above the critical temperature, by P. de Heen. The superior limit of pressure of superheated steam before the passage into the liquid state is the simple prolongation of the curve expressing the variation of the tension of saturated vapour.—On the production of ammonia in the soil by microbes, by Émile Marchal. Nitrification takes place in three principal stages, which may be described as ammonisation, nitrosation, and nitratation, resulting in the production of ammonia, nitrites, and nitrates respectively from the organic nitrogen. Ammonisation takes place essentially under the influence of microbes living in the upper layers of the soil. In arable land, the action of bacteria is predominant. The *Bacillus mycoides*, the most energetic of these, exerts a double activity in the production of ammonia, being ammonising in the presence of nitrogenous organic matter, denitrifying when embedded in easily reducible substances such as nitrates.

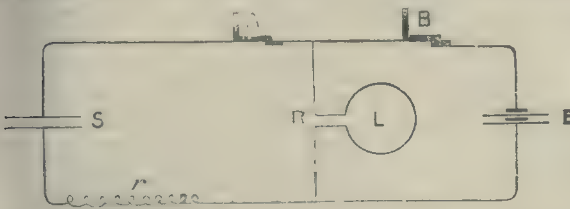
SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 1.—"On the Flow in Electric Circuits of Measurable Inductance and Capacity; and on the Dissipation of Energy in such Circuits." By Alfred W. Porter, B.Sc., Demonstrator of Physics in University College, London. Communicated by Prof. G. Carey Foster, F.R.S.

The arrangement of the apparatus in the experiments described was as follows:—

L is a coil possessing self-inductance; S, a condenser; R, an inductionless resistance; E, a battery; and A and B are two contact pieces of a pendulum interruptor. A and B are initially closed; B is first broken; A is then broken, and the charge remaining in the condenser is measured by discharging it through a galvanometer. The time interval between the two ruptures



can be varied one twenty-thousandth of a second at a time, and the manner of discharge of the condenser under the circumstances is thus determined. Curves were obtained showing (1) a merely leaking discharge; (2) the critical discharge that just fails to ever have negative values; (3) the critical discharge that just fails to be oscillatory; and (4) a thoroughly oscillatory discharge.

The differential equation to be satisfied by the discharge is—

$$\left(L\frac{d^2}{dt^2} + \rho\frac{d}{dt} + \frac{1}{S}\right) Q = 0,$$

where Q is the charge at any instant and ρ is the dissipation constant.

The solution of this for the case of oscillations is of the form—

$$Q = Q_0\epsilon^{-mt} \sec\phi \cos. (pt + \phi).$$

Experiment shows that the rate of damping is much greater than that calculated from the above, assuming that the wire circuit is the only seat of dissipation of energy. The explanation offered is that dissipation also takes place in the dielectric of the condenser. In accordance with this it is possible to reproduce the experimental curve by increasing the value of ρ from 28 ohms (the wire resistance in a particular case) to 59·4 ohms. The observed time period in this case is ·009147 seconds; the time period calculated on the above assumption is ·009154 seconds.

Experimental curves have also been obtained when iron rods are inserted in the coil. Their chief characteristics are—

(a) A decrease in time-period as the discharge progresses.

(β) Much more rapid decrement.

That (β) is only very partially due to eddy currents in the iron, was shown by repeating with a brass rod inserted in the place of iron.

Experiments are also in progress in connection with circuits of negligible capacity; a Wheatstone's bridge method being employed.

SYDNEY.

Linnean Society of New South Wales, June 28.—The following papers were read:—Notes on Australian Coleoptera, with descriptions of new species, part xiii., by the Rev. T. Blackburn.—Notes on the family Brachyscelidæ, with descriptions of new species, part ii., by W. W. Froggatt. This paper deals with Schrader's two genera Opisthoscelis and Ascelis; the two original species of Schrader are re-described, and two new species of Ascelis are added.—On the habit and use of nardoo (*Marsilea Drummondii*, R. Br.), together with observations on the influence of water-plants in retarding evaporation, by T. L. Bancroft. The author has visited the south-western corner of Queensland, journeying there *viâ* South Australia and eastward across Queensland. He first encountered nardoo in quantity near Lake Copperamana on Cooper's Creek, where, as over all the drainage-areas of the Cooper, Diamantina, and Georgina Rivers, the Blacks still make use of it as in the days of Burke and Wills. As originally stated, the plant thus utilised under the name of nardoo is a Marsilea; though doubt has been cast upon the statement under the idea that it would be impossible to obtain the involucres (sporocarps) in sufficient quantity to serve as food; and by those who took this view the seeds of *Sesbania aculeata*, Pers., were supposed to furnish the nardoo of Burke and Wills. In a day one could gather about a hundredweight of the dried rhizomes of the Marsilea with involucres attached, yielding perhaps about forty pounds weight of the latter. It was found also that the nardoo did not grow in permanent water nor in swamps, but in country subject to inundation; and from specimens brought home vigorous pot plants were reared without difficulty. As regards floating water-plants retarding evaporation, the author has made experiments with a series of gallon glass cells, some furnished with *Lemna*, *Azolla*, and *Nymphæa gigantea*, others without, and with some of each placed out of doors in the sun, and others in the shade and under cover, he found that evaporation was neither retarded nor hastened by the presence of the aquatic plants.

PARIS.

Academy of Sciences, August 14.—M. Lœwy in the chair.—On the Tubulane, a truffle of the Caucasus, by M. A. Chatin. This is a new variety of the *Tirfezia Boudieri*, which is so widely distributed in North Africa and Arabia. The roundness of the spores resembles that of the African variety, whilst the surface markings are those of *Tirfezia Boudieri Arabica*. The new variety, found about Tiflis and Baku, and sent from there by the French Consul, M. Auzepi, has been named *Tirfezia Boudieri Auzepii*. The natives call it Tubulane. It is the size of a large walnut, and its good quality and low price renders it fit for European export.—Study of the microbian origin of purulent surgical infection, by MM. S. Arloing and Ed. Chantre. Purulent surgical infection has for its essential agent the ordinary microbes of suppuration (streptococci in the cases examined). If microbes other than the preceding ones exist in the wounds, they complicate the purulent infection, but are not necessary to its development. To produce purulent infection, the streptococcus must assume the virulence which it possesses in the acute and grave forms of puerperal septicemia, and not that shown in erysipelas. There is a suspicion of etiological relations between surgical purulent infection, puerperal septicemia, and erysipelas, but it is not known as yet where and how the transformation of the pathogenic properties of the streptococcus take place which enables it to produce alternately these different clinical states.—On a product of incomplete oxidation of aluminium, by M. Pionchon. Submitted to the action of an oxy-hydrogen blow-pipe flame containing an excess of hydrogen, aluminium oxidises with vivid incandescence and is changed into a substance of a greyish-black colour, in which the ratio of the weight of oxygen to that of the aluminium has a value approaching 0·6, and therefore very different from 0·888, the value characteristic of alumina. A treatment of the substance with hydrochloric acid gave rise to a disengagement of hydrogen and the formation of aluminium chloride in solution, besides leaving an insoluble residue. A quantitative estimation of these various constituents leads to the conclusion that the grey substance contains small quantities of freer aluminium and alumina, and consists of a new oxide of aluminium, probably represented by the formula $Al_6O_7 = Al_2O, 2Al_2O_3$, which may be either a mixture or a compound.—On a new reaction of eserine, and a green colouring matter derived from the same alkaloid, by M. S. J. Ferreira da Silva.—Synthetic preparation of citric acid by the fermentation of glucose, by M. Charles Wehmer.—On the changes which have taken place in the glacier of the Tête Rousse since the catastrophe of Saint-Gervais, of 12th July, 1892, by MM. A. Delebecque and L. Duparc. Nearly all the water from the glacier escapes at present at the bottom, so that there is no immediate danger of its accumulation. But this state of things is only temporary. The valley of Montjoie appears to be exposed to a catastrophe similar to that of 1892, which must happen sooner or later. No preventive measures seem possible. A diligent watch, and an evacuation of the valley at the proper times seem to be the sole remedies.

BERLIN.

Physical Society, June 16.—Prof. von Helmholtz, President, in the chair.—Prof. Kœnig gave an account of the construction of the newest forms of artificial larynx, more especially the one described by Prof. Julius Wolff. The capabilities of the latter were demonstrated on a patient operated upon by Prof. Wolff, who could not only speak continuously so as to be audible throughout the whole lecture-room, but could also sing. The president pointed out that this case fully substantiated his theory as to the production of vowel-sounds, inasmuch as the tones being initially produced by a vibrating elastic membrane acquired their vowel quality solely by means of the varying shapes of the resonating buccal cavity. Prof. Fraenkel exhibited a man who without either a natural or artificial larynx could both speak and repeat the whole alphabet. It appeared that the patient while speaking swallowed at frequent intervals and ejected forcibly a considerable mass of air from the open end of the trachea. Careful investigation showed that there was no communication between the trachea and œsophagus; Prof. Fraenkel referred the power of speech to the existence of a fold of mucous membrane at the end of the widened pharyngeal cavity, at about the level of the former larynx, which was thrown into vibration during speech. It had not been possible to ascertain whence the patient obtained the air requisite to keep the fold in vibration; possibly the air which had been swallowed sufficed for this purpose. Dr. Krigar Menzel had, in conjunction with Dr. Raps, studied the motion of plucked strings by the method previously employed for stroked strings. The string is stretched across the long axis of a narrow brightly illuminated slit, and thereby casts a small punctiform shadow on a screen. When the string swings, a curve is traced on the moving screen, which admits of being fixed by photography. The speaker developed the theory of strings vibrating as above, and deduced formulæ which corresponded to the curves obtained. Dr. Wien spoke on the upper limits of wave length for radiant heat as based upon certain properties of Hertz's waves and the second law of thermodynamics.

Physiological Society, June 23.—Prof. du Bois Reymond, President, in the chair.—Prof. Koenig exhibited the two patients with extirpated larynx as described in the preceding report of the Physical Society.—Dr. Benda gave an account of his microscopical investigations on the development and function of the mammary gland. He had studied the development on five- and eight-month-old calves, and the functions on cows and bitches during lactation, and arrived at the conclusions that the mammary gland must be regarded as a tubular gland, and that there is no evidence of a new formation of cells during its activity. The idea that the secretion of milk depends on a breaking-down of the gland cells cannot apparently be supported by the results of microscopic investigation.

July 7.—Prof. Holowinsky, of Warsaw, spoke on a microphone he had constructed, by means of which it is possible to render audible rhythmic movements of long period, such as the cardiac impulse, the radial and carotid pulse, &c. The action of the instrument was demonstrated on several persons.—Dr. Baginsky had studied the relation of the nerves to the sensory end-organs in the case of the glossopharyngeal and olfactory nerves, by section of the nerves and subsequent investigation of the behaviour of the terminal sensory cells in each case. In the case of the tongue he found these cells unaltered after degeneration of their nerve; whereas in the case of the olfactory cells, both they and the whole mucous membrane degenerated after removal of the olfactory bulb. He, however, attributed the result in the latter case to injury of the ethmoid artery.

July 21.—Dr. Lilienfeld made a further communication on the clotting of blood arrived at by an examination of fibrine and of fibrinogen which he regarded as a nucleo-albumin. He came to the conclusion that some substance is present in normal blood which leads to clotting in presence of minimal amounts of calcium chloride. Dr. Paul Strassmann had studied the mechanism of the closing of the ductus Botalli in man, dogs, and cats, and found it dependent upon the anatomical arrangements of the entrance into the aortic arch, supporting his views by a series of preparations. Dr. Jacobs had investigated the action of extracts of a series of animal tissues on the number of the white corpuscles. He found that extracts of liver, kidney, pancreas, and thyroid had no effect on their number, while, on the other hand, extracts of spleen, thymus, and the marrow of bones, after producing a short fall, led to an increased production of leucocytes which continued for many hours, and was marked both in the peripheral as well as in the central blood-vessels and in the heart.

BIRDS IN A VILLAGE.

Birds in a Village. By W. H. Hudson, C.M.Z.S., author of "Idle Days in Patagonia," "The Naturalist in La Plata," &c. (London: Chapman and Hall, Limited, 1893.)

MR. HUDSON would probably think it a doubtful compliment if we were to say that his last book is as good as either of the two which preceded it. But to say that "Birds in a Village" is not equal to "Idle Days in Patagonia," and not to be mentioned in the same breath as the charming "Naturalist in La Plata," by no means implies that it is other than a pleasantly readable book, with here and there—more particularly in the chapter which gives the title—graphic sketches of the habits of the birds he watched in his ideal country village, such as only a close and loving observer of Nature, and a practised writer, can give.

The unregenerate man may perhaps at first be a little inclined to rebel when he finds his insular ignorance of languages brought, he may think, rather too obtrusively home to him by untranslated Spanish poetry and a critical discussion on the superiority of Melendez to Tennyson in a chapter in which he had hoped to forget himself and his failings among blackbirds and thrushes. But any resentment he may have felt for the moment will be forgotten as he looks over the fence into the cottage garden and sees the hedge sparrow feeding the young cuckoo with caterpillars, "like dropping a bun into the monstrous red mouth of the hippopotamus at the Zoological Gardens," or lolls on the moss in the wood to watch through Mr. Hudson's binocular the jay, "high up amongst the topmost branches," as he "flirts wings and tail, and lifts and lowers his crest, glancing down with wild, bright eyes . . . inquisitive, perplexed, suspicious."

By the time he has wandered up the brook-side to the corner where "buttercups grew so thickly that the glazed petals of the flowers were touching, and the meadow was one broad expanse of yellow," and has caught sight of the kingfisher, "like a waif from some far tropical land," flying off "so low above the flowery level that the swiftly vibrating wings must have touched the yellow petals," he will have realised that he is in the company of one of the devoted worshippers of Nature, by whom "where'er they seek her she is found," and for whom every spot—country village, London park, or solitary South American plain—is "hallowed ground."

As might be expected of a man who has lived on such impartially friendly terms with living things of many kinds that, after lying helpless and alone miles away from any one, with a revolver bullet in his knee, he could find relief to his pain in the knowledge that the poisonous snake which had shared his rug with him through the night had got off in the morning without inhospitable treatment at the hands of his returning friend, Mr. Hudson rejects as "utterly erroneous" the "often quoted dictum of Darwin, that birds possess an instinctive fear of man," and quotes in support of his view—in which we entirely concur—the tameness of the moorhens in St. James's Park.

The wood-pigeons—in the country the wariest of birds, in London tamer if possible than the sparrows—are even stronger witnesses for him. It is said that the Paris wood-pigeons, which are as common and tame there as with us, and make frequent excursions to neighbouring country places, the moment they leave the precincts of the town assume their natural wildness, putting it off again the moment they return to the children and *bonnes* in the Tuileries Gardens.

By-the-bye, in connection with wood-pigeons we have a very small bone to pick with Mr. Hudson. Since Science has become a religion it was only to be expected that the religious parasite—*odium theologicum*—would develop new forms to suit. It has done so, and too many recent scientific works—notably one of the best modern bird books—are disfigured by sneers at other writers.

A charm of Mr. Hudson's writings hitherto has been, and we hope it always will be, that he has kept himself free from smallnesses of the kind. But there is "a little pitted speck" in this last fruit which we have never noticed in any of his earlier gatherings, and, microscopic though it is, we are sorry to see it. He is perfectly justified if he thinks it so in speaking of the wood-pigeon—the "deep, mellow crush" of whose note in Campbell's ears "made music that sweetened the calm" of the birchen glades he loved—as "*that dismal croaker.*" But having done so he ought not to fall foul of a brother ornithologist and his ancestry, and to throw Wordsworth at his head because he has ventured to write disrespectfully in *Blackwood* or *Macmillan* of the note of the greenfinch. We hope that Mr. Hudson will feel grateful to us for a friendly reminder that people who live in glass houses should not throw stones.

Mr. Hudson, as many another writer has done, protests in impassioned language against the practice of eating larks. The song of the "blythe spirit" of meadow and corn-land is as sweet to us as to him; and, being unfashionable enough not to appreciate, as every self-respecting diner should do, *mauviettes en surprise aux truffes*, or in any other dainty form, we may venture with a clear conscience to express a doubt whether the supply of larks to the markets affects appreciably, if at all, the numbers remaining to breed in England. Wherever they may come from, there can be no question the number of immigrants in winter is almost incredible. The most striking feature of a partridge drive at the headquarters of the sport, in the flat country round Thetford and Brandon, towards the end of the season, is the sight of the apparently interminable flocks which stream over the waiting guns. We have heard it said by a large landowner in the district, an ardent bird-lover, that it is no exaggeration to say that larks there are, when the early corn is first shooting, a nuisance to the farmers scarcely less serious than are the rats in more enclosed parts.

Space will not allow us to follow Mr. Hudson into the interesting questions touched upon in his later chapters. We fear that, whatever may lie before our children in good times to come, the dimming eyes of our own generation will not be refreshed by the sight of the glancing colours of exotic kingfishers reflected in English streams, nor can we ourselves look forward with any great confidence to an early realisation of Mr. Hudson's dream of artificial birds'-eggs of such magic perfection that schoolboys seeing them will rob birds'-nests no longer, though we agree with him in thinking that the volatile colours of most eggs when blown, make collections of but little lasting value.

There is in "Birds in a Village," unless we are mistaken, something which may possibly prove of more practical interest to lovers of good works of natural history than any such agreeable speculations.

"Travel fever" is a malady easily caught. It is recurrent, and when once caught, seldom completely shaken off until life energy begins to fail and a man nears the starting time for his last journey. There are touches—sometimes rather pathetic—in the book before us which suggests that it was written under the influence of an unusually sharp attack. A few words from a little girl in St. James's Park, "Oh, how I love the birds!" were enough to start the writer wandering "somewhat aimlessly" about the country till he stumbled on his nightingale-haunted village and stopped there. "I could not," he writes, "longer keep from the birds, which I, too, loved, for now all at once it seemed to me that life was not life without them, that I was grown sick, and all my senses dim; that only the wished-for sight of birds could medicine my vision; that only by drenching it in their melody could my tired brain recover its lost vigour."

The chapter headed "Chanticleer" is as symptomatic as the passage quoted above. Mr. Hudson tries seriously to persuade himself and his readers that he likes being awakened at three o'clock in the morning by his neighbours' cocks! When he believed himself listening to their crowings he was in a trance, having his eyes open. His body may have lain "on high ground in one of the pleasantest suburbs of London," but he was himself thousands of miles away—lying on the cliff-edge, dropping stones to startle the great coots of Patagonia, riding at a swinging gallop through rustling seas of giant thistles into the "mysterious, extra natural, low level plain, green and fresh and snaky, where horsehoofs made no sound," or gazing up at the starry skies of the Pampas. The sounds of which he was really conscious were the concerts of crested screamers, or the dance music of La Plata rails.

Mr. Hudson will not think we wish unduly to disparage his "Birds in a Village" if we express a hope that circumstances may allow him soon to let Nature have her way, and that before long he may be able again to show us, on larger canvas, other collections of sketches of scenes less easily accessible.

In these days of high pressure one of the most serviceable qualities that a man can possess is the power of self-abstraction—to be able to throw work and worries on one side and bury himself in other interests. In "Endymion," when the hero's father found money difficulties gathering round him, and his political hopes failed at what had seemed the very moment of realisation, he committed suicide "because," says the author, "he had no imagination." The power which could convey Lord Beaconsfield himself at the time of a crushing defeat back to the formal terraces and gardens of the Bradenham of his boyhood, and enable him there to forget himself in the hopes and fears of beings of his own creation, is a gift of the gods to the few. A love of Nature—its best substitute—is a possession scarcely less precious, and one to which every parent may do much to help his children.

For such an education many more ambitious works could be better spared than the transcripts from the less known pages of "God's great second volume" which Mr. Hudson so well knows how to write. T. D. P.

A MATHEMATICAL MISCELLANY.

Mathématiques et Mathématiciens, Pensées et Curiosités. By A. Rebière. Second edition. First edition, 1889. (Paris: Nony et Cie, 1893.)

THIS work, originally issued in 1889, contains quotations from various writers on the study or philosophy of mathematics, together with some anecdotes and problems on the subject. The first edition consisted of but 280 pages, but advantage has been taken of a new issue to make additions which have more than doubled its size. Save for a brief section on the history of mathematics, the work is almost entirely a compilation, and no attempt is made to connect together the extracts or draw any inferences therefrom. The reader thus has the advantage of being able to begin anywhere, but the effect of many hundreds of short and disconnected paragraphs is somewhat jerky. To form such a miscellaneous collection, drawn from writers of all ages, must have involved extensive preparation and years of reading. M. Rebière may be congratulated on the result of his labours, for the volume is undoubtedly interesting, though of somewhat unequal merit.

It is divided into four parts. The first is mainly devoted to remarks on the philosophy of mathematics—by far the greater portion being drawn from French sources. In our opinion this is the best section of the book, since many of the extracts here given would otherwise be practically inaccessible; moreover it is always instructive to read the opinions of writers like Condillac, Mdme. de Staël, Rousseau, and Comte, and not the less so when their knowledge of the subject discussed is rather superficial. At the same time we think that a reader may reasonably expect detailed references to the sources of the quotations, and certainly the value of the collection would be increased thereby.

The section on the history of mathematics, which is placed at the close of this part, is a mere travesty of the subject. We cannot suppose that M. Rebière, when writing his work, seriously thought that Galileo, Kepler, Newton, and Leibnitz were the only mathematicians outside France who should be mentioned as having been eminent in the last five hundred years; that among over forty names given as representing contemporary mathematicians not a single foreigner should find a place; or that five French papers were the only current periodicals of any importance (had not M. Rebière ever heard of *Crelle's Journal?*). In the second edition the names of Huygens, Euler, Gauss, and Jacobi, together with those of a few European contemporaries are added, but though M. Rebière in his preface specifically calls attention to these additions, we consider he would have been better advised to have omitted this section rather than give a sketch which is so unsatisfactory.

The second division of the work is of a very miscellaneous character, ranging from quotations and anecdotes to a note on the superstition that thirteen is an unlucky number, and a remark that Newton's fluxions is not, as might be inferred from the title, a medical work. Any citation involving a geometrical term or a number seems to be regarded as worthy of a place here: thus the observation of a diplomatist that the straight course is not always the shortest way is regarded as a geometrical anecdote. Such examples abound, but it is an unusual stretch of langunge to call them mathematical.

The third division commences with some quotations which might have been equally well placed in the first part of the book. Most of it is, however, devoted to what are called paradoxes and singularities; such as a mnemonic verse for recollecting the approximate value of π, that the number six hundred and sixty-six is supposed to be connected with Antichrist, that a map of the heavens is now being prepared by photography, that two and two do not truly make four because the units used can never be exactly alike, that since it is very cold at the North Pole it might be thought that it was very hot at the South Pole, that Cardan's solution of a cubic equation is useless for determining real roots, and so on. Such a collection of assertions and extracts—mostly unaccompanied by comment or reference — will probably be less attractive to the mathematician than to the general reader.

The book concludes with some problems, classified according to subjects. In general, only the enunciations are given. Thus, in arithmetic, we have the question how many digits are used in paging a volume of one thousand six hundred and forty-five pages; in algebra, the question of finding the number of rabbits and pheasants when altogether among them there are thirty-five heads and ninety-four feet; in optics, the determination of a point equally illuminated by two given luminous points; in mechanics, the curve of pursuit, and in higher (!) mathematics, the question of finding the sum to which a centime would amount in eighteen hundred and eighty-nine years at compound interest at the rate of five per cent. a year. Some "recreations" and celebrated problems are also included: historical notes on these or references are either absent or so incomplete as to be practically useless, though they would add greatly to the interest of the questions. Moreover, it seems desirable to add a warning that questions of this kind—such as the inscription in a circle of a regular polygon of seventeen sides, the theory of the knight's tour on a chess-board, and the formation of perfect numbers—are of a totally different character to the common catch of the time occupied in reaching the top of a pole twenty metres high by a snail which each day crawls up three metres and each night slips down two metres. Here, however, conundrums and problems of all degrees of difficulty are indiscriminately mixed up together. In spite of this obvious criticism the collection is a good one, and well adapted to stimulate interest.

The printing and get-up of the book are admirable, while the foregoing sketch will, we think, enable the reader to form a general idea of its contents. We have already stated that, in our opinion, its chief value lies in the citations on the philosophy of the subject; the scientific worth of the rest is more questionable, but it forms an amusing collection of assertions and notes concerning mathematics which may be commended to those interested in such matters.

OUR BOOK SHELF.

Grasses of the Pacific Slope, including Alaska and the Adjacent Islands. Part II. By Dr. George Vasey, Botanist to the U.S. Department of Agriculture. Issued June 1, 1893. (Washington: Government Printing Office, 1893.)

THIS is the fourth part of a series of plates and descriptions of the rarer American grasses which has been issued by the United States Department of Agriculture. The first volume was devoted to the species of Texas and the south-west, and the present volume, which is now finished, contains plates and descriptions of the grasses of California, Oregon, Washington, and the north-western coast, including Alaska. Dr. Vasey, who for many years was head of the department at Washington, died before the present volume was issued. He was a native of Yorkshire, who emigrated to the Western States in early life. For many years Dr. Vasey lived in Illinois, and was one of the leading authorities on the plants of the Western States. He was already advanced in years when he became a government servant, and made a special study of the grasses.

The number of grasses of the Pacific Slope reaches nearly two hundred species. They are nearly all specifically distinct from the species east of the Mississippi River. A considerable number of the grasses of the mountain regions of California, Oregon, and Washington reappear in the mountains of Idaho, Montana, and the interior Rockies.

The interior of California is a dry region, verging in the extreme south into desert country, and is very deficient in grasses. In the present part there are descriptions and plates of 1 Schimdtia, 1 Phippsia, 1 Arctagrostis, 2 species of Agrostis, 3 of Calamagrostis, 2 of Deschampsia, 1 Trisetum, 1 Danthonia, 6 of Melica, 2 of Pleuropogon, 1 Uniola, 15 of Poa, 1 Colpodium, 2 of Dupontia, 1 Glycera, 1 Atropis, 3 of Festuca, 2 of Bromus, 1 Agropyrum, 3 of Elymus, and 1 Gymnostichum. Only two of the species are British, *Calamagrostis neglecta* and *Elymus arenarius*. The descriptions are mainly drawn up by Mr. L. H. Dewey. We wish the department could see its way next to issue a complete synopsis of all the grasses of thé United States. J. G. B.

Reveries of World History, from Earth's Nebulous Origin to its Final Ruin; or, the Romance of a Star. By T. Mullett Ellis. (London: Swan Sonnenschein and Co., 1893.)

IT is difficult to estimate the place of this book in scientific literature. The object of its publication is apparently to give the world the benefit of moralisings very similar in style to those indulged in by Mr. Richard Swiveller of *Old Curiosity Shop* fame. But there is no substance in the book whatever. From the first to the last page the author meanders on with wearisome platitudes expressed in high-flaunting style, obscuring a line of fact in a page of padding. This is the manner in which he is carried away on the subject of the origin of man.

"He came like an apparition. Whence? Who shall say? Who shall dare, out of his absolute knowledge, to declare his origin, his ancestry?

"What hopes had he in that dreary desolation? What thoughts? What ambitions?

"What a being! What a nature, his! How noble his form! Between the mammoth and himself, between the animals that he chased and he, what a chasm in the scale of creation!"

So the rhapsody continues, without backbone or argument of any kind. Mr. Millett Ellis probably means well. Indeed, his literary effort may be highly appreciated by people who mistake verbiage for eloquence. To us, however, the contents appear to be in a nebulous condition like that which existed when, to use Mr. Ellis's words, "The chaos of earth circled in the vastness."

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Publication of Physical Papers.

THE discussion started by Mr. J. Swinburne in NATURE of June 29, seems to have wandered from its original purpose, and from the points suggested in your article of July 13. It is the duty of an investigator in any branch of Natural Science to publish the results of his research if they appear to be both new and of sufficient interest. He has three courses open to him. He can write a book, relying on the advertisements of his publisher and on reviews to inform other workers that such a book exists. His space is unlimited, but he cannot make sure of a circulation unless by presentation copies. He may communicate his results to a scientific society. His space is somewhat limited, but he secures a definite circulation, and an opportunity for discussion. Or he can communicate them to some technical journal, securing generally the maximum circulation, but with considerable restriction as to space.

The publication of books needs no comment, and was alluded to by Mr. Swinburne. Mr. Buchanan thinks that the publication of papers in all branches of science is in as unsatisfactory a state as that of physics, and advocates the central organ suggested by Dr. Oliver Lodge, and referred to by Mr. Swinburne as a last resort. But the real question seems to be one of facilities for the publication of original communications, not of abstracts or reprints; and these not of general science, but of physics. Mr. Swinburne has given reasons which render a purely physical journal impossible, unless it be endowed or subsidised, as in the case of the excellent *Physical Review* of the Cornell University. Nothing could be more complete than the publication of chemical researches; and geology, astronomy, biology, and physiology, though untainted by the patentee, and treated often as a hobby rather than as a study, seem to be well provided for.

Exhaustive and important physical researches, such as those of Ewing on Magnetism, should undoubtedly be communicated to the Royal Society. The Transactions, it is true, are very expensive, and the circulation appears to depend largely on presentation copies, unless an abstract or reprint appears elsewhere. Work done at University laboratories is in many cases appropriately communicated to local societies, the circulation is almost negligible, and the majority of the papers are never heard of by outsiders. The Physical Society appears to offer the greatest facilities, and to publish its proceedings in the best possible manner—first through its own Proceedings, secondly by a recent arrangement with the *Philosophical Magazine*, thirdly by a number of reprints issued to the author, and last, but not least, by the admirable report which is sent to and printed by a number of technical journals, and which appear regularly in NATURE. Dr. Lodge thinks that "the method of publication invented, or at any rate adopted, by the Physical Society of London" is "well worthy of imitation." Not of imitation surely, for to multiply societies will hinder rather than facilitate reference to the published papers. The valuable work of the Physical Society needs extension. The double publication in the *Philosophical Magazine* and in the Proceedings seems to be somewhat wasteful. A selection of its heavy mathematical papers might be offered by the Society to the *Philosophical Magazine*; and thus leave room in its Proceedings for publication, in addition to its present contents, of papers accepted for printing, but not necessarily for reading and discussion; and for abstracts or for full publication of the more important physical papers of the societies of Cambridge, Oxford, Dublin, Edinburgh, and Glasgow. The Institution of Civil Engineers publishes a number of "selected papers"; these are either unsuitable for reading and discussion at a meeting, or are of minor importance. They receive perhaps less attention from London members who frequently attend the meetings, and who rarely read the Proceedings, but they secure as wide a circulation as those which are accepted for reading. A very successful departure was made by the Institution of Electrical Engineers in the publication, early in August, 1892, of a paper by Mr. J. Swinburne on "Problems of Commercial Electrolysis." At the meeting on November 10, this paper was taken as read, and a useful and vigorous discussion followed, occupying two evenings.

By the brief but careful and always accurate abstract of the papers, and by the no less excellent though much more care-demanding report of the discussion, an unusually wide circulation of the chief points of all communications to the Physical Society is secured. The lithographed reports are sent gratuitously to any technical journal that cares to publish them. Abstracts of "selected papers" could be sent out in the same way, and could be made with far less trouble, since, unlike the report which is issued a few days after each meeting, they could be dealt with at leisure; the abstract might indeed be furnished by the author, though I am not sure that this is advisable. The Physical Society seems in every way admirably fitted for the publication of physical papers, and no greater facilities for experimental demonstration could be desired than those which are so freely afforded to the authors of papers read before it.

Mr. Basset suggests that the London Mathematical Society would be a good medium for the publication of physical papers. May I protest against confusion between the two sciences, and I am sure that many pure mathematicians, though from a different point of view, will agree with me? There was once and I believe still exists, a "science" called Microscopy. It was divided into two factions, strongly opposed to each other. These were named, reciprocally I suppose, "The Glass and Brass School," and "The Slug and Bug School." The one regarded the *navicula* and the *grammatophora* as having been specially created to afford test objects for showing off the performance of favourite instruments; the other considered immersion objectives and correcting adjustments as mere tools, the use of which must be learned; and regarded polariscope attachments and mechanical stages as toys. The problem worker, it would be ambiguous to call him a mixed mathematician, finds in physics an unlimited material for problem-setting. In many cases he accidentally makes an original contribution to physical science, he frequently gives most valuable finishing touches to the experimental work of others, and occasionally actually retards progress, as in alternate current electrical engineering, by introducing complications on insufficient data, to the discouragement and confusion of the experimental worker. Good tools are in themselves a delight to a good workman; no true physicist can disregard mathematics, even in those branches which are to him useless. But the aims differ, and the sciences should be distinct.

There need be no rivalry whatever with the Royal Society. Elaborate memoirs do not admit of discussion, and it would be a pity to burden the Physical Society with the expense of printing them, when the Royal Society can so well afford to give them place in its Transactions. The strict rules of the Institution of Civil Engineers against the publication of its papers in technical journals before they have appeared in its own proceedings, and the similar rule of the Royal Society, so far as its Transactions are concerned, may perhaps be in keeping with the unapproached prestige of these institutions. But the Royal Society issues proofs of its Proceedings after the papers have been read, and the Institution of Mechanical Engineers and other societies send out proofs of their papers with the simple condition that they are not to be reprinted until the communications have been actually read. The Physical Society tacitly adopts the latter course, sending proofs before the meeting to those who are likely to take part in the discussion. The only objection to the free publication of a paper *before* it is read and discussed, is that a discussion may take place prematurely in the technical journals; but with the exception of NATURE, these are in touch with so few branches of physics, that but little harm would be done.

I venture to think that the publication of physical papers can be carried out most efficiently by means of the present procedure of the Physical Society; that with a few modifications it could deal with all the more important physical papers annually published in this country; and that such centralisation is very desirable. Such modifications I beg to suggest are the following:—(1) Let mathematical papers, *i.e.*, those which consist of problems in mixed mathematics rather than pure physics, be offered to the *Phil. Mag.*, publishing the conclusions, with a reproduction of any resulting diagram, in brief abstract in the journal. (2) Let papers be invited not only for reading during the winter season, but for publication at intervals throughout the year, whenever enough matter has been collected to fill a number, as is done in many other publications. (3) Let selections be made from these for reading, on the grounds [*a*] of scientific importance, [*b*] suitability for discussion, [*c*] experimental demonstration. (4) Reprint in abstract, or occasionally in full, papers read before other societies (excepting, of course, the Royal Society).

I feel that some apology is due for making these suggestions elsewhere than at an annual general meeting of the Physical Society, but the attendance at the meetings is no measure of the important work which this society does in the publication of physical papers, and as these suggestions arise directly out of the discussion which has arisen in your columns, they may perhaps not be out of place there. ALEX. P. TROTTER.

28, Victoria Street, Westminster.

The Definition of "Heredity."

WHEN all the world is ringing with the words "heredity" and "inheritance," it is natural to feel some surprise and amazement on hearing from even so high an authority as Dr. Hurst that they are expressive of nothing but the incoherence of ideas emanating from confused brains. Perhaps as a student of Darwinism I may be allowed a little space in your columns to suggest that there is an alternative view to that held by Dr. Hurst.

His position I understand to be this: No force of any kind except natural selection is at work to preserve the form of organisms from alteration. Does he mean to confine the application of this statement to organisms existing under stable conditions, or would it have equal force in the probably numerous cases where temporary changes in circumstances occur? Now it cannot be denied that there is some factor of considerable power controlling the variations of species from the normal type; but that it is a natural selection, as ordinarily understood, seems to me to be at least open to discussion. If, without the action of natural selection all species are liable to react to any change in their environment, there is no reason against and very great probability in favour of many species having been destroyed by the advent of new conditions followed by the substitution of new forms quite ill-adapted to the old conditions. What would then be likely to happen should the original circumstances return? Two alternatives are possible under Dr. Hurst's view. Either the form resulting from the first change must be lost, or it must again become modified; but the chances are infinite against any approximation to the original organism being reached unless there be some tendency towards a return to former types.

If we adhere to the opinion that "heredity is something more than mere family likeness," and not quite comparable to the "tendency of all weathercocks to point to the south-west," we are at once freed from the difficulty, and can see how a species might outlive many temporary changes in the form of influences to which it might be subjected. In order that species may be modified to suit new permanent surroundings it is obviously unnecessary that the variations arising among the individuals shall be very frequent, and, when organisation and environment are in agreement, it is equally obvious that the fewer the departures from the normal type the better will it be for the species. If, then, the tendency is strong in all organisms to conform to an ancestral type, whenever there is a merely temporary change of environment the chances of some at least of the individuals leaving unmodified descendants, when the old conditions reassert themselves, is vastly increased; and if meanwhile some other individual families have become somewhat modified, then the number of species in existence may also have been increased. Of course I am supposing that the period during which abnormal conditions of life remain in force shall not extend sufficiently to allow all the unmodified individuals to be eliminated by the action of natural selection.

If I have been successful in my argument, I think it will be clear that the force which I should designate by the term "heredity" cannot be described as a tendency fostered by natural selection; for, while any influence it may exert antagonistic to the development and continuance of species will be counteracted by natural selection, the benefits it may confer are almost entirely prospective, and therefore do not fall within the range of the force which tends to preserve favourable variations.

I conceive that the definition of the word "heredity" should be—the tendency, more or less strong according to the age of the species, to follow certain types, exhibited by all organisms, and that it is no mere abstract idea devoid of objective existence, but a force the importance of which we are not yet able to fully grasp.

In conclusion I should like to mention a point with regard to the case of Saturnia which has, I think, been overlooked. What has really been proved is simply the fact that the insect is extremely susceptible to modification by change of food. If some entirely new food-plant, if possible chosen from an entirely different order, could be found as a substitute for either species of Inglans, and the result were carefully watched, the experiment could not fail to be instructive, I will not say conclusive.

Rochdale, August 19. J. SPENCER SMITHSON.

Sexual Colouration of Birds.

THE recent controversy in your columns with regard to the non-inheritance of acquired characters opens up the question whether the principle of natural selection operates universally in the animal kingdom, or whether we must involve other causes to supplement it. In Dr. Hurst's letter of August 17 (p. 368) is a sentence which seems to embody what has generally been understood as Darwinism: "If anything has ever been rendered certain in biology by prolonged experiment and observation, it is the fact that specific characters are maintained constant by selection, and that alone." But how does this agree with Dr. Wallace's theory of accessory plumes? This theory he himself thus expresses ("Darwinism," p. 293): "The fact that they have been developed to such an extent in a few species is an indication of such perfect adaptation to the conditions of existence, such complete success in the battle for life, that there is in the adult male, at all events, a surplus of strength, vitality, and growth-power which is able to expand itself in this way without injury." Here we have two entirely different views of what is meant by the struggle for existence. According to Dr. Hurst it is incessant; let its operation cease, and the characters of the species become speedily obliterated. According to Dr. Wallace a victorious species may leave the arena, and rest upon its laurels. But if natural selection ceases to work in this field, why not in others? The colours, it is true, may be due merely to waste products turned to account, but the annual growth of the peacock's plumes—often nearly five feet in length—must require a great expenditure of vital force.

In Brown's "Thier-reich" it is stated that even in ordinary cases moulting is not unaccompanied with danger to the bird. And this is not all: the secondary wing feathers of the argus pheasant are developed to such an extent that they are said "almost entirely to deprive the bird of flight" ("Descent of Man," vol. ii. p. 97). The theory by which Darwin himself accounted for these phenomena, viz. that the female selected the most brilliantly coloured male as her partner, explained the facts, but failed for want of sufficient evidence that any such selection took place. I cannot think that the two forms of sexual selection, by battle and by female preference, conflict, since the hen bird might well admire the combination of fine plumes and warlike prowess.

There is, besides, Mr. Stolzmann's theory that it is to the advantage of the species that the number of males should be kept down, since bachelor males persecute the hen bird upon the nest. This assumes what is not well proved, that males largely outnumber females. But a very large proportion of the species in which the cock-bird is highly decorated are polygamous, and in these cases the number of males is obviously excessive. Mr. Stolzmann's theory in no way conflicts with Darwin's, but rather supplements it. Moreover, it is hardly more than an extension of Dr. Wallace's view that the dullness of the female's plumage is due to her need of protection, which in the case of the male is less necessary. Both Darwin's theory and Mr. Stolzmann's require further evidence, but they each have the merit of suggesting a cause for the constancy of the same plumage through successive generations.

Scourie, Lavig, N.B., August 24. F. C. HEADLEY.

Bird's Steering Methods.

MR. HEADLEY'S suggestion (NATURE for July 27) that gulls sometimes steer by dropping one foot, is, it seems to me, hardly tenable, for so small a rudder acting on so thin a medium as air would be of little effect. And although I have seen many gulls under very varying circumstances, I have never seen them even appearing to direct their course in such a manner.

That birds, to a great extent, steer by changing the position of their centre of gravity is undoubtedly correct, and it is especially true of birds with long narrow wings, such as the petrels and sheerwaters. The albatross exhibits this method to perfection, and anyone who has watched this bird circling far and wide, will have noticed what an angle the outstretched, almost motionless, wings make with the level of the water, an angle frequently as great as 45°

The flexion of the body is, I take it, of comparative little help, difference in force or direction of wing stroke being the main method by which birds direct their course.

The wings may act synchronously, a change in the direction of one wing causing it to act with more or less force than the other, while such change might be so slight as to elude the eye, or even a camera. A humming-bird will hover about a cluster of blossoms, now hanging motionless, now circling right or left around the flowers, and as there is no turn of the head or swaying of the body, it is evident that the directed force lies in the wings, although their presence is indicated by a mere hazy blur. The body is usually held at an angle of from 30° to 45° with the vertical, and the tail is kept closed, being indeed rarely spread, except when the bird is darting about in the air.

The use of wings is well shown by the crows, which in fall and winter roost in great numbers on the other side of the Potomac, and may be seen towards sunset winging their way homeward from their feeding places. When the wind is light, the crows fly high and steadily, but in windy weather they may be seen beating back, just skirting the tree-tops, apparently to take advantage of any favouring eddy that may exist near the earth. As the birds dart up and down, and from side to side, one can clearly see the wings open and close, and unless my eyes are very deceptive, the two wings are by no means always opened to the same extent.

The principal use of a bird's tail seems to be to effect vertical changes in direction, and while birds with moderately long tails usually have a more graceful, gliding flight than their abbreviated relatives, they are no more expert on the wing. The flight of the forked-tailed swallow is more pleasing than that of the short-tailed chimney swift, but the swift is quite as much at home in the air as is the swallow.

Birds with unusually long tails, such as the hornbills, are apt to be but indifferent flyers.

Washington, D.C., U.S.A., August 14. F. A. LUCAS.

The Early Spring of 1893.

THE exceptional character of the spring of this year has already been described in these columns. It seems worth the while to inquire to what extent the warm weather commencing in March affected the times of flowering of our native flora. The Botanical Section of the Halifax Scientific Society has now for seven years, since 1887, kept a record of all plants observed by its members growing within the limits of the Halifax parish. This, it may be mentioned, is of considerable extent, perhaps measuring six miles by twelve or more. Thus, the record affords a means of comparing the dates of flowering this spring with those of previous years. Of course these will not coincide with records from other districts, as the South of England, but they will satisfy the necessary condition of such an inquiry, viz. that the district should be of limited extent so that the time of flowering of any species in one year is practically the same throughout it. In addition there is the advantage that the drought was not so great as to retard or kill the vegetation. On the other hand, such a record must necessarily be open to error; a plant may have been in bloom some time before it was met with; only a comparatively few species have been recorded *every* year without a break; some days often intervene between a flower being in bud and in bloom, and the record may possibly, without saying so, refer to the former. However, these errors are partly constant, and may be partly eliminated by neglecting the rarer species, which have only been noted two or three times.

In February almost the only plant to flower was the hazel, seen this year on the 15th, and last year fourteen days later.

In March twenty different species were observed in flower; of these only half had been previously recorded in March, the other half being equally divided between April and May. Coltsfoot (*Tussilago Farfara*) and *Salix Caprea* appeared at the usual time within the first week; the daisy was not noticed till the 31st, whereas it had previously been found on the 29th; but almost all the others were very much earlier than usual. The average was more than eighteen days before the earliest previous record. This is borne out by the fact that the same elm (*Ulmus montana*) was in flower this year (on March 9) twenty days earlier than last year. In some cases, *e.g. Stellaria Holostea*, *Ranunculus acris*, and *Alchemilla vulgaris*, the period was increased to as much as five weeks.

There were a few apparent exceptions, but they may certainly be put down to accident or rather neglect. The chickweeds, *Cerastium triviale* and *Stellaria media* escaped notice till April, groundsel had previously been noted earlier than April 9, and shepherd's purse was no doubt in flower early in April, but was ignored till May came in.

The effect of the weather became more pronounced throughout April. Excluding the common "weeds" just mentioned, every flower was at least a fortnight before its earliest previous record, and the list of twenty-five species is composed almost entirely of May flowers; in fact the only exceptions were the wood sorrel and the marsh marigold, in flower on the 5th and 8th, or antedated fourteen and twenty days respectively. On an average the flowers of April were 25·5 days earlier than in any of the previous years. The exact dates of a few of the commonest are appended.

Cardamine pratensis	April 8, 1893;	May 10–15,	1887–92
Scilla nutans	,, 13, ,,	,, 1,	1887
Lychnis diurna ...	,, 13, ,,	,, 10,	,,
Veronica Chamaedrys	,, 13, ,,	,, 15,	1888
Allium ursinum ..	,, 16, ,,	,, 5,	,,

Thirty-five fresh species were added in May, twelve of which are usually June flowers. By this time, however, it became difficult to keep a complete record, so that about half-a-dozen appear to flower later this year than in one or other of the previous years. Again excluding these, the remainder flowered seventeen days earlier than before. From a consideration of those given below it would appear that the season was about three weeks earlier at the beginning of the month, and a fortnight at the end.

Cytisus Scoparius ...	May 6, 1893;	May 13, 1890
Orchis mascula ...	,, 6, ,,	,, 14, 1892
Geranium Robertianum	,, 6, ,,	,, 17, 1887
Trifolium pratense ...	,, 6, ,,	,, 28, 1892
Quercus Robur ...	,, 6, ,,	,, 29, 1887
Crataegus Oxyacantha	,, 7, ,,	,, 29, 1888 (But usually June 3–9.)
Rhinanthus Crista-galli	,, 27, ,,	June 9, 1890
Chrysanthemum Leucanthemum ...	,, 27, ,,	,, 9, ,,

In June the advance still remained about a fortnight, taking twenty seven species into consideration, but an increasing number have to be left out owing to the impossibility of recording all as soon as they appeared. Ten out of the twenty-seven had previously belonged to the catalogue of flowers appearing in July.

Lychnis Flos cuculi ...	June 10, 1893;	June 17–26,	1887–92
Silene Cucubalus ...	,, 10, ,,	,, 26,	1888
Rosa canina	,, 10, ,,	,, 28,	1887
Centaurea nigra ...	,, 10, ,,	July 2,	1889
Lonicera Periclymenum	,, 15, ,,	,, 2,	1892
Spiræa Ulmaria ...	,, 15, ,,	,, 2,	1889
Digitalis purpurea ..	,, 15, ,,	June 24,	1890
Valeriana officinalis...	,, 17, ,,	,, 24,	,,
Achillea millefolium..	,, 26, ,,	,, 27,	1892

In July there seems to be no evidence for the maintenance of the advance; the flowers were then appearing at their normal season, *e.g.*—

Campanula rotundifolia	July 8, 1893;	July 2–15, 1887–92
Calluna Erica	,, 22, ,,	,, 19, 1887
Jasione montana ...	,, 1, ,,	,, 2, 1892
Cnicus arvensis ...	,, 1, ,,	,, 2, 1889
Scabiosa succisa ...	,, 22, ,,	,, 23, ,,
Galeopsis Tetrahit ...	,, 15, ,,	,, 16, 1892

The general result is, then, that the season was three weeks early in March, but that by the first of April the advance had increased to four weeks; this was maintained through most of the month, but May day was only some three weeks in advance; the fall continued slowly through May and June with an average advance of a fortnight. In July, however, the effects of the early spring had ceased to have any effect. These conclusions are more likely to err on the side of moderation, for it must be remembered that the flowering time this year has been contrasted not with the average, but with the earliest record of previous years.

W. B. CRUMP.

Mr. Love's Treatise on Elasticity.

THE second volume of Mr. Love's treatise will doubtless be reviewed in NATURE in due course; but in the meantime I desire to make some observations upon certain criticisms, which this work contains, on my own papers on thin elastic shells, plates, and wires.

The theory of thin plates, and shells in the form given by Mr. Love, is based upon those of Kirchhoff, Saint-Venant and Clebsch. All these theories are incomplete and defective, and depend upon certain assumptions and approximations which have been called in question, and are by no means free from difficulty. An attempt has been made—see pp. 92 and 207—to remove these objections by classifying the different cases which arise, but whatever may be thought of the success of this explanation, it requires the reader to wade through a long and complicated analytical investigation before he is in a position to apply the theory.

On the other hand, the method of expansion originally employed by Poisson, and afterwards by myself, coupled with the hypothesis that the stresses R, S, T may be *treated* as zero, is one of great power, and, as I showed a few years ago, enables an approximate theory to be *completely* worked out as far as terms involving the cube of the thickness of the plate or shell, and Mr. Love is forced to admit on p. 236 that his own theory is incapable of doing this. It is true that Clebsch and Saint-Venant have raised objections against the method of expansion which I cannot regard otherwise than as frivolous ones; but although an account of the first class of theories is no doubt desirable, it is much to be regretted that Mr. Love has allowed his bias against the second class of theories to lead him to adopt a mode of treatment which greatly increases the difficulties of the subject, is less perfect, and which, I fear, will retard its further progress by throwing unnecessary obstacles in the way of students.

On pp. 238 and 262, Mr. Love imagines that he has detected an error in my own work as regards the values of T_1, T_2 (in his notation P_1, P_2), but this conclusion is not warranted. His investigation in § 353 expressly supposes the vibrations to be non-extensional, whereas in the investigation by which I have calculated, T_1, T_2 by means of the variational equation, extension is expressly supposed to take place. If it were desired to calculate the values of T_1, T_2 by the variational method in the case of inextensibility, it would be necessary to start with the corresponding form of the potential energy, and to take account of the fact that δu, δv, δw are not independent, either by means of indeterminate multipliers or by elimination. The two cases are therefore not parallel, and the so-called test is nugatory. If a direct test were desired, it could be supplied by means of the theory of the radial vibrations of a cylinder worked out to a second approximation.

The only other point to be noticed is that in the case of a bent wire the values of the three couples given by Mr. Love on p. 169 disagree with those obtained by myself. Mr. Love *assumes* these couples to be respectively proportional to the changes of curvature and twist, and he then proceeds to calculate the latter quantities in terms of the displacements by a method which leaves nothing to be desired as regards elegance and conciseness and comprehensiveness. But he can scarcely be said to have given anything which can be called a proof that these couples are *actually* proportional to the above-mentioned quantities; and a new and independent investigation is much to be desired.

A. B. BASSET.

Hotel de Russie, Bad-Ems, Nassau, Germany, August 23.

An Appeal to Mathematicians.

SINCE I have commenced the study of the "Ramayana" (the great Sanskrit epic) in original Sanskrit, and its translations, epitomes, and commentaries by renowned European scholars, I have been struck with the inadequacy the western scholars of Indian chronology have shown in fixing the date of Rama.

I cannot but admire the method used by our modern Egyptologists in computing the dates of Egyptian chronology, and correcting the discoveries of some of the earlier researches in that interesting branch of knowledge. Having discovered it written in some old MSS. that in the reign of a certain king some remarkable comet or eclipse was observed, or a building was erected pointing to a certain star in the heavens, which has since changed position, &c., &c., our scholars have obtained sufficient data to compute with tolerable correctness a more or less trustworthy date for that king.

There is no doubt that such refined discoveries could never have been made if this branch of knowledge were left alone with simple historians or simple chronologists—I mean, no light would have been thrown over the pages of the dark history of Egypt had not astronomical methods been employed to solve the vital questions of Egyptian history.

I am very much grieved to see that the chronology of India has not at all been touched by any scientific investigator whose conclusions could be relied on, though Indian chronology is now proving to be far more interesting than the chronology of any other country or nation of the world. India has now the honour of being under the benign rule of the British nation, so forward in scientific matters; then does it not give grief to the lover of India to see this important branch of past history so much being neglected?

The second half of the eighteenth century and the first quarter of this nineteenth century had seen a few benefactors of India, like Profs. Colebrooke, Muir, Wilson, &c., whose discoveries brought to light much interesting information about ancient India. It was a misfortune for India of to-day that among those benefactors they were few who could bring in mathematical astronomy to solve some vital points of Indian chronology. Prof. Colebrooke wrote some valuable essays on the Hindu system of astronomy, but it was our misfortune that his attention was not drawn towards the Indian chronology; otherwise he was a man who could have done much to settle the dates of Hindu chronology.

Rama has been a personage of Indian history whose existence has not yet been denied by any scholar, yet see what conflicting dates have been given to this mighty king of ancient India: Sir William Jones places Rama in the year 2029 B.C., Tod in 1100 B.C., and Bentley in 950 B.C. Govvesio would place him about the thirteenth century before the Christian era!

Govvesio computes his date thus:—"From Rama to Sumitra, the contemporary, as it appears, of Vikramaditya (B.C. 57), fifty-six kings ruled in succession. By allowing on a reasonable computation an average of a little more than twenty years to each reign, we arrive at the thirteenth century before the Christian era." ("Ramagana," vol. i. Introduction.) While it is questionable whether any king by name of Sumitra ever reigned in India, or was a contemporary with Vikramaditya, Govvesio confesses—"But to this opinion I do not intend to attribute more weight than that of a probable conjecture." And so it is; and a ridiculous one, too; for Sumitra[1] was not a king contemporary with Vikramaditya, but *she* was one of the queens of the king Dasaratha, the father of Rama.

I now come to the point of my appeal. Here is the position of the seven primary planets at the birth of Rama plainly written in Canto xix. of the first book of the Ramagana: Moon in Cancer, Sun in Aries, Mercury in Taurus, Venus in Pisces, Mars in Capricornus, Jupiter in Cancer, and Saturn in Libra. The problem to be solved is this: Taking January 1, 1894, as starting-point, compute when the planets occupied the positions respectively referred to above, and when again they will occupy the same positions in the future? Though the problem appears to be a simple one of permutation and combination, but I must confess with regret that none

[1] "Sumitra" is a Sanskrit word of feminine gender. As Sanskrit was a living language at the time of Vikramaditya, though perhaps only within higher circles of society, yet it could not be believed that this word might have been so degenerated as to be used in opposite gender at that time.

of the professors of mathematics here with whom I have come in contact have taken the trouble of solving it, and therefore it is that I am appealing in this strain to the mathematicians who have any interest in the chronology of India.

Many interested scholars have expressed their desire for the solution of this problem. Thus says Prof. Schlegel: "I leave to astronomers to examine whether the parts of the description agree with one another, and if this be the case, thence to deduce the date. The Indians place the nativity of Rama in the confines of the second age (Treta) and the third (Dwapara); but it seems that this should be taken in an allegorical sense. . . . . We may consider that the poet had an eye to the time in which, immediately before his own age, the aspects of the heavenly bodies were such as he has described."

Besides the positions of the planets at the birth of Rama, I have a few more data concerning the Hindu system of the division of heavens, which I shall be glad to communicate to any gentleman who is acquainted with that system, and expresses a desire for the same.

Lahore, August 8.

Arrangements for Work of Chemical Section of the British Association.

MANY of your readers will be interested to know that M. Moissan has kindly arranged for a demonstration of the properties of fluorine, and his method of isolating the element, at a meeting of the Chemical Section of the British Association at Nottingham, in September. M. Moissan will also exhibit some specimens of the diamonds he has artifically produced.

We also hope to have at least two discussions, one on Bacteriology and its related chemical problems, which Prof. Percy Frankland has been so good as to promise to open, and another on explosions in coal mines, with special reference to the "dust theory." This, Prof. Harold Dixon has kindly consented to introduce.

Permit me to remind authors that they will greatly facilitate the arrangements for the satisfactory grouping of papers at the sectional meeting, if they will communicate as early as possible with the Secretaries, Burlington House.

The Bacchus Marsh Boulder Beds.

YOUR issue of August 10 contains an interesting communication by Messrs. Officer and Balfour on the glacial boulder beds of Bacchus Marsh in Victoria, in which they are referred to as triassic. May I be permitted to point out that this is erroneous? It is true that the late Dr. O. Feistmantel in his earlier descriptions of, and references to, the flora of these beds, regarded them as triassic, but this was the natural consequence of their correlation with the Talchir group of India, which he then ascribed to the trias. In 1886 it was shown by Dr. Wagner and myself sumultaneously that the true correlation of the Talchir group was with the marine beds below the Newcastle coal measures of New South Wales; the Bacchus Marsh boulder beds are consequently upper carboniferous, and form part of the traces of the upper carboniferous glacial period which have been recognised in Australia, Africa and Asia. The matter will be found fully dealt with in pages 120–123 and 191–214 of the second edition of the "Manual of the Geology of India," just published by the Indian Geological Survey.

S.S. *Rena*, August 19. R. D. OLDHAM.

Old and New Astronomy.

WHILE thanking you and your reviewer for your very courteous and appreciative notice of the "Old and New Astronomy," I should like to be permitted to point out that the chapter on the sun's surroundings was printed and was in the hands of the public before my connection with the work commenced. Your reviewer suggests that I ought to have corrected certain statements in this earlier part of the volume, but I felt that it was sufficient to mention in the preface that I did not agree with *all* Mr. Proctor's conclusions, and it must be obvious that it would neither have been an easy nor a gracious task to have attempted in the latter part of a book to criticise the statements and theories of the deceased author of the earlier chapters.

Your reviewer suggests that the proof I give of the very small density of the Orion Nebula is "vitiated by the fact that it is impossible to estimate the gravitational effect of the dark matter in interstellar space." I conclude that he does not refer to dark matter within the area of the nebula, for this would only add to the mass of the nebula and to the observed velocities of the stars in its neighbourhood. That dark matter evenly distributed in space around would not interfere with the gravitational effect of the nebula will be evident to those who remember that the attraction of a hollow spherical shell on a body within it may be neglected, since the attractions in all directions balance whatever is the position of the body within the spherical shell. The stars around the nebula seem to be distributed in all directions, and it cannot be supposed that in each case there is a gravitating dark mass on the side away from the nebula which counterbalances the attraction of nebulous matter.

Your reviewer cannot, I think, have seen Dr. Huggins's photograph of the spectrum of the Orion Nebula and the stars involved in it, or he would not suggest that the bright lines in the spectra of the stars could be due to the overlapping by tremors and atmospheric disturbances of the spectrum of the nebular matter. The bright nebula lines distinctly widen and brighten in the neighbourhood of the stars. One is therefore forced to conclude that the bright lines when they cross the stellar spectra belong to the stars.

A. C. RANYARD.

August 19.

THERE is nothing in my review that implies the desirability of Mr. Ranyard having modified any of Mr. Proctor's *conclusions* in the chapter on the sun's surroundings; I simply pointed out an *error of date* that should have been corrected.

I do not see any reason for supposing that the quantity of matter in the area we call the Orion Nebula is greater than that in any other arbitrarily selected equal area in space, and the evidence seems conclusive that the whole of interstellar space is a meteoric *plenum*. This being so, there is no reason why stars in the neighbourhood of the nebula should have their velocities in any way affected by it. Mr. Ranyard proves that there is no great difference in density, but does not touch the question of the absolute quantity of matter involved.

I have not seen Dr. Huggins's original photographs of the spectrum of the Orion Nebula, and the stars involved, nor have I seen direct copies of them, but I have examined other photographs in which the star and nebula spectra appear, and have also visually examined the spectra, and am by no means convinced that the nebula lines are brighter and wider in the stars.

THE REVIEWER.

An Old Device Resuscitated.

IN the Astronomical Column of the current number of NATURE a description is given from *L'Astronomie*, of M. Jarson's method of giving equatorial motion to a telescope mounted on an ordinary altazimuth stand. This method will be found figured and described by Lord Lindsay, now Earl Crawford, in the *Monthly Notices* of the Royal Astronomical Society, xxxvii. 1, Nov. 10, 1876. Moreover, in a note appended to the paper, Lord Lindsay says that since writing it his attention had been drawn to the fact that this principle of mounting had been described by Sir George Airy in *Monthly Notices*, xv.

Laws of Error in Drawing.

I SHOULD be obliged if you allow me to state in the next issue of NATURE, to prevent any misconception of the extent of those "compulsory errors" alluded to in my article printed in the current number, that I am able to specify such, with equal particularity, as they occur in the following additional figures, viz.:—The cylinder, the ringed cylinder, the oblong, the octagon, cone, hexagonal pyramid, octagonal pyramid, triangle (solid). Also in those figures framed of square-sectioned woodwork that have the following shapes, viz. square, cross, triangle, arch, hexagon, pentagon, circle. Again, that they are observable in all forms which are complexities of the primal forms above given; and, moreover, I have traced them clearly in the draughtsmanship of Orientals, and even in the drawing of the greatest painters.

ARTHUR L. HADDON.

Glenavon, Cornwallis Avenue, Clifton Vale, Bristol, August 25.

THE INFLUENCE OF EGYPT UPON TEMPLE-ORIENTATION IN GREECE.

I HAVE shown in former articles that in our own days and in our own land the idea of orientation which I have endeavoured to work out to the best of my ability for Egypt still holds its own. It is more than probable, therefore, that we shall find the intermediate stages in those lands whither by universal consent Egyptian ideas percolated.

Among these lands Greece holds the first place. It is perhaps proper that I should state here that the view as to the possibility of temple orientation being dominated by astronomical ideas first struck me at Athens and Eleusis, and that I endeavoured to settle the question by studying the Egyptian monuments, because they were the only monuments I could study as a stay-at-home, thanks to the labours of the French Commission and of Lepsius.

When I found that the same idea had been held by Nissen, and that the validity of it seemed to be beyond all question, I consulted my friend, Mr. F. C. Penrose, particularly with regard to Greece, as I knew he had made a special study of some of the temples, and that, being an astronomer as well as an archæologist (for, alas, they are not as I think they should be, convertible terms) it was possible that his observations with regard to them included the requisite data.

I was fortunate enough to find that he had already determined the orientation of the Parthenon with sufficient accuracy to enable him to agree in my conclusion that that temple had been directed to the rising of the Pleiades. He has subsequently taken up the whole subject with regard to Greece in a most admirable and complete way,[1] and has communicated papers to the Society of Antiquaries, February 18, 1892, and more recently to the Royal Society, April 27, 1893, on his results.[2]

The problem in Greece was slightly different to that in Egypt; we had not such a great antiquity almost without records to deal with, and moreover the feast calendars of the various temples presented less difficulty.

There was no vague year to contend with, and in some cases the actual dates of building were known within a very few years. Mr. Penrose has been convinced that in Greece, as in Egypt, the stars were used for heralding sunrise. He writes :—

"The object the ancients had in using the stars was to employ their rising and setting as a clock to give warning of the sunrise, so that on the special feast days the priests should have timely notice for preparing the sacrifice or ceremonial, whatever it may have been :

> "Spectans orientia solis
> Lumina *rite* cavis undam de flumine palmis
> Sustulit," &c.

In Greece, not dominated by the rise of the Nile, we should not expect the year to begin at a solstice but rather at the vernal equinox. I have shown that even in pyramid times in Egypt the risings of the Pleiades and Antares were watched to herald the equinoctial sun; it is not surprising, therefore, to find the earliest temples in Greece to be so oriented. Mr. Penrose has found the following :—

η Tauri (The Pleiades)	Archaic temple of Minerva	Athens[3]	R	1530
	Asclepieion	Epidaurus	R	1275
	The Hecatompedon site of Parthenon	Athens	R	1150
	Temple of Bacchus	Athens	R	1030
	Temple of Minerva	Sunium	S	845

[1] In the lists of temples which follow all the orientations were obtained from azimuths taken with a theodolite, either from the Sun or from the planet Venus. In almost every case two or more sights were observed, and occasionally also the performance of the instrument was tested by stars at night. The heights subtended by the visible horizon opposite to the axes of the temples were also observed.

[2] See NATURE, February 25, 1892, and May 4, 1893.

[3] R indicates a rising, and S a setting observation.

				B.C.
Antares	Heræum	Argos	R	1760
	Earlier Erechtheum	Athens	S	1070
	Temple at	Corinth	S	770
	Temple on the mountain .. .. Jupiter Panhellenius	Ægina	S	630

Here we find the oldest temple in a spot which by common consent is the very cradle of Greek civilisation.

It has also been shown that in Khu-en-Aten's time the new sun-temple at Tell el-Amarna was oriented to Spica, Spica too, we find, so used in Greece in the following temples.

				B.C.	
Spica	The Heræum at	Olympia	R	1445	
	Nike Apteros	Athens	S	1130	
	Themis ...	Rhamnus	R	1092	
	Nemesis ...	Rhamnus	R	747	
	Apollo	Bassæ	R	728	Eastern doorway
	Diana	Ephesus	R	715	

When owing to precession the sun's spring equinox place had receded from Taurus and entered Aries, in Egypt the equinoxes were no longer in question, since the solstitial year was thoroughly established, and consequently we find no temples to the new warning star α Arietis.

In Greece, however, where the vernal equinox had now been established as the beginning of the year, we find a different state of things, no less than 7 temples oriented to α Arietis are already known.

α Arietis	Minerva	Tegea ...	R	1580	
	Jupiter Olympius	Athens ...	R	1202	
	Jupiter	Olympia ...	R	790	
	Temple (perhaps Juno)	Platea ...	S	650	
	Jupiter	Megalopolis	S	605	
	Temple at the harbour ...	Ægina ...	S	580	
	Temple on Acropolis of Mycenæ	...	R	540	Eastern doorway
	The Metroum ...	Olympia ...	S	360	

The above are all intra-solstitial temples, that is, the sunlight as well as the light of the star can enter them, and this enables us to note a certain change of thought brought about in all probability by the artistic spirit of the Greeks. The Egyptian temples were all dark, often with the statue of a god or a reptile obscure in the naos, and many were oriented so that sunlight never entered them. Mr. Penrose points out that almost all the Greek temples are oriented so that sunlight can enter them, of such temples we have the following 27.

7 examples from		Athens.	1 example from		Sunium.
3	,,	Olympia.	1	,,	Corinth.
2	,,	Epidaurus.	1	,,	Bassæ.
2	,,	Rhamnus.	1	,,	Ephesus.
2	,,	Ægina.	1	,,	Platæa.
2	,,	Tegea.	1	,,	Lycosura.
1	,,	Nemea.	1	,,	Megalopolis
1	,,	Corcyra.	2	,,	Argos.

Now in all these Greek temples, instead of the dark naos of the Egyptian building, we find the cella fully illumined and facing the entrance. Frequently, too, there was a chryselephantine statue to be rendered glorious by the coloured morning sunlight falling upon it, or if any temple had the westerly aspect by the sunset glow.

It was perhaps this, combined with the later invention of water clocks for telling the hours of the night, which led to the non-building of temples resembling those at Thebes and Denderah facing nearly north. Still there are scattered examples; one of very remarkable importance, as it is a temple oriented to γ Draconis 1130 B.C., built therefore not very long after the temple M at Karnak, and this temple is at Bœotian Thebes! A better proof of the influence exerted by the Egyptians over the temple building in Greece could scarcely be imagined. As Mr. Penrose remarks:—

"Thebes was called the City of the Dragon, and tradition records that Cadmus introduced both Phœnician and Egyptian worship."

It would be very surprising if we assume, as we are bound to do, that these temples to stars were built under Egyptian influence, that Sirius should not be represented among them, that being the paramount star in Egypt at a time when we should expect to find her influence most important in Greece. Still, I have shown already that as the Greek year ignored the solstice, the use of Sirius as a warning star for all purposes of utility would not come in. Mr. Penrose finds, however, that in spite of this Sirius was used for temple worship.

"Leaving the solar temples, we find that the star which was observed at the great Temple of Ceres must have been Sirius, not used, however, heliacally—although this temple is not extra solstitial—but for its own refulgence at midnight. The date so determined is quite consistent with the probable time of the foundation of the Eleusinian Mysteries and the time of year when at its rising it would have crossed the axis at midnight agrees exactly with that of the celebration of the Great Mysteries.

"It is reasonable to suppose that when, as in the case of Sirius at Eleusis, brilliant stars were observed at night, the effect was enhanced by the priests by means of polished surfaces."

Another question. Does the star follow the cult in Greece as it does in Egypt?

In Greece we find the following:—

"The star α Arietis is the brightest star of the *first sign of the Zodiac*, and would therefore be peculiarly appropriate to a temple of Jupiter. The heliacal rising of this star agrees both with the Olympieium at Athens and that at Olympia. There is a considerable difference in the deviation of the axes of these two temples from the true east; but this is exactly accounted for by the greater apparent altitude of Hymettus over the more distant mountain at Olympia.[1]

"The Pleiades are common to the following temples of Minerva, viz. the Archaic temple on the Acropolis, the Hecatompedon, and Sunium. In the two former it is the rising, the latter the setting star.

"There must have been something in common between the temples at Corinth, Ægina, and Nemea. The two last, at any rate, are reputed temples of Jupiter."

The Greek side of the inquiry becomes more interesting when the connection between the orientation of the intra-solstitial temples and the local festivals are inquired into; in Egypt this is all but impossible at present.

A temple oriented to either solstice can only be associated with the longest or with the shortest day; if the temple points to the sunrise or sunset at any other period of the year the sunlight will enter the temple twice whether it points to the sunrise or sunset place.

Now Mr. Penrose finds that in Greece as in Egypt the initial orientation of each intra-solstitial temple was to a star, and this would, of course, secure observations of the star and the holding of an associated festival at the same time of the year for a long time. But when the precessional movement carried the star away they would only have the sun to depend on, and this they might use twice a year. It is possible, as Mr. Penrose remarks, there would have been no reason for preferring one of these solar coincidences to the other, and the feast could have been shifted to a different date if it had been thought more convenient." He goes on to add, "It would appear that something of this sort may have taken place at Athens, for we find on the Acropolis the Archaic temple, which seems to have been intended originally for a vernal festival, offering its axis to the autumnal sunrise on the very day of the great Panathenaia in August.

"The Chryselephantine statue of the Parthenon, which temple followed on the same lines as the earlier Hecatompedon (originally founded to follow the rising of the Pleiades after that constellation had deserted the Archaic temple alongside), was lighted up by the sunrise on the feast to the same goddess in August, the Synæcia, instead of some spring festival, for which both these temples seem at first to have been founded.

"The temple at Sunium, already quoted for its October star-heralded festival to Minerva, was oriented also axially to the sun on February 21, the feast of the lesser mysteries."

I have had to insist again and again that in the case of the Egyptian temples the stated date of foundation of a temple is almost always long after that in which its lines were laid down in accordance with the ritual. No wonder then that the same thing is noticed in Greece.

"In about two-thirds of the cases which I have investigated the dates deduced from the orientations are clearly earlier than the architectural remains now visible above the ground. This is explained by the temples having been rebuilt upon old foundations, as may be seen in several cases which have been excavated, of which the archaic Temple of Minerva on the Acropolis of Athens and the Temple of Jupiter Olympius on a lower site are instances. There are temples also of the middle epoch, such as the examples at Corinth, Ægina, and the later temples at Argos and at Olympia (the Metroum at the last named), of which the orientation dates are not inconsistent with what may be gathered from other sources."

The problem is, moreover, helped in Greece by architectural considerations, which are frequently lacking in Egypt, of two temples it can be shown, on this evidence alone, that one is older than the other. Such an appeal strengthens my suggestion that two of the temples of the Acropolis Hill were oriented to the Pleiades, by showing the older temple to point to an earlier position of the star group. To these Mr. Penrose adds another pair at Rhamnus, where he has found that there are two temples almost touching one another, both following (and with accordant dates) the shifting places of Spica, and still another at Tegea.

J. NORMAN LOCKYER.

[In a letter received from Mr. Penrose, giving me permission to use the above quotations from his preliminary account, he makes the following interesting statements:—

"In my paper sent to the Royal Society there was a passage which seems to make it practically *certain* that heliacal stars were connected with the intrasolstitial temples as derived from Greek examples alone, independent of the powerful aid of the Egyptian cases.

"That the first beam of sunrise should fall upon the statue centrally placed in the adytum of a temple or on the incense altar in front of it on a particular day, it would be requisite that the orientation of the temple should coincide with the amplitude of the sun as it rose above the visible horizon, be it mountain or plain.

"That a star should act as time-warner it was necessary that it should have so nearly the same amplitude as the sun that it could be seen from the adytum through the eastern door, if it was to give warning at its rising, or to have a similar but reversed amplitude towards the west, if its heliacal setting was to be observed; and it follows that in the choice of the festival day and the corresponding orientation, on these principles, both the amplitude of the sun at its rising and that of the star

[1] With regard to a temple of Minerva using α Arietis at Tegea, Mr. Penrose writes:—"Minerva is allowed by the poets to have been able to use Jupiter's thunder, so this is no misappropriation of the star. Juno also seems to have claimed the use of α Arietis as at Samos, and at Girgenti it suits the orientation of the temple of Juno better than Spica. But Spica seems to have been connected with the worship of Juno and Diana in their more strictly female capacity."

eastwards or westwards as the case might be would have to be considered in connection with one another.

"From what has been said it is obvious that in the intrasolstitial temples the list of available bright stars and constellations is in the first instance limited to those which lie within a few degrees of the ecliptic, and it will be found that in the list above given and those which follow, if we omit Eleusis, where the conditions were exceptional, all but one of the stars are found in the zodiacal constellations. A very great limit is imposed in the second place by one of the conditions being the heliacal rising or setting of those stars from which the selection has to be made. So that when both these combined limitations are taken into account it becomes improbable to the greatest degree that in every instance of intrasolstitial temples of early foundation of which I have accurate particulars, being twenty-eight in number and varying in their orientation from 21° N. to 18° 25′ S. of the true east. There should be found a bright heliacal star or constellation in the right position at dates not in themselves improbable unless the temples had been so oriented as to secure this combination.

"I have just been looking into the number of possible stars which could have been used, *i.e.* within the limits of the greatest distance from the ecliptic that could have been utilised.

"The stars which could have been utilised in addition to the seven which serve for nearly thirty temples are ten only, viz.:—

Aldebaran.	β Libræ.
Pollux.	α Libræ.
β Arietis.	α Leonis.
β Tauri.	γ Leonis.
α and β Capricorni as a group.	β Leonis.

"If the orientations had been placed at random would not our thirty temples have made many misses in aiming at these seventeen stars, it being necessary also to hit exactly the heliacal margin? And would they have secured anything like a due archæological sequence?

"Another point is this:—

"Whenever a star less than first magnitude is used (Pleiades only excepted) it has been necessary to secure coincidence to give it several more degrees of sun depression than in the cases of Spica and Antares."]

BRITISH ASSOCIATION MEETING.

FURTHER information is now to hand as to the scientific work which has been arranged for the approaching meeting of the Association at Nottingham.

In Section A two papers have been received on "Physics Teaching in Schools." G. H. Bryan contributes an interesting paper on "The Moon's Atmosphere and the Kinetic Theory of Gases," showing that every planet must be throwing off some of its atmosphere on the kinetic theory, though at an exceedingly slow rate in the case of the larger bodies. Prof. J. J. Thomson will exhibit and explain a new form of air-pump, which will be of interest to sections A and B. Prof. Viriamu Jones is sending a paper on "Standards of Low Electrical Resistance."

As reported by Prof. Emerson Reynolds on p. 416, Section B has been most fortunate in securing a promise from M. Moissan to describe and demonstrate the preparation and properties of fluorine. This will probably have the effect of inducing chemists from all parts of this country to visit Nottingham, as the demonstration has never yet been made in this country, and is of almost unique importance and interest. It is anticipated that M. Moissan's communication will be put down for Monday, September 18, and will probably include the exhibition of his artificial diamonds. Prof. Percy Frankland will introduce the discussion on "Bacteriology in its Chemical Aspects" on Friday, 15, and amongst other papers will be one by J. T. Wood, on "A New Bran Bacterium." Tuesday, 19, will probably be mainly devoted to the discussion of "Colliery Explosions," introduced by Prof. H. B. Dixon, one of H.M. Commissioners. On this day further communications on flame researches are also expected. The President's address is put down for twelve o'clock on Thursday, September 14; it will deal essentially with "The Comparative Chemistry of the Elements," specially treating of carbon and silicon, and of silico-organic researches; showing further that it is possible in the light of recent knowledge to fill in some details of the chemical history of the earth. Dr. Phookan has promised a description of his recent researches on the "Rate of Evaporation of Bodies in Different Atmospheres."

In Section C Prof. Hull will read a paper "On the Water-supply of Nottingham"; Mr. Walcot Gibson, one on "The Geology of British East Africa"; Prof. Brögger will describe "The Eruptive Rocks of the Christiania District"; E. T. Newton, "The Trias Reptiles"; Prof. Sollas, "The Carlingford Rocks" and "Glendalough Amphibolite"; R. M. Deeley, "The Drifts of the Trent Valley"; and Prof. Iddings, of Chicago, "The Petrology of a Dissected Volcano." Amongst other papers already promised are the following:—"The Gypsum Deposits of Nottinghamshire," by A. T. Metcalfe"; "Derbyshire Toadstone," by H. A. Bemrose; "Mollusca from the English Trias," by R. B. Newton; "Transported Mass of Chalk in Boulder-clay of Culworth, in Huntingdonshire," by A. and C. Cameron; "Some Volcanic Rocks of South Pembrokeshire," by F. T. Howard and E. W. Small; "Midland Trias," by Dr. A. Irving; "Limestone Inclusions in the White Sill," by E. T. Garwood.

Two further papers are sent in for Section D—one by Prof. Gilson, of Louvain, on "Cytological Difference in Homologous Organs," and one by G. B. Rothera, on "Some Vegetal Galls and their Inhabitants."

In connection with Section E the exhibition of the 120 pictures painted on an Antarctic sealing expedition by Mr. Burn-Murdoch has been referred to. The discussion on the "Limits between Geography and Geology" will be introduced by Mr. Clements R. Markham, Pres.R.G.S. Mr. Delmar Morgan will summarise our knowledge of Thibet, and Miss Taylor will describe her recent journey in that country. Mrs. Grove will read a paper on the "Islands of Chiloë." Mr. E. G. Ravenstein will give an account of recent African travel; and a large number of other papers are promised, many of which are of more than ordinary interest. The illustration of many of these papers by lantern photographs will be a special feature.

With respect to Sections F and G there is at present nothing further to add to the original statement made a few weeks since.

In Section H Mrs. Grove promises a paper, "The Ethnographic Aspects of Dancing." Prof. Boyd Dawkins, who is now on a visit to Glastonbury, intimates his intention to discuss the scientific bearings of the discoveries made at the lake village in that neighbourhood; and, in order that the members may be better able to understand the structural details of the woodwork exposed in the course of the excavations, Dr. Munro proposes to give an illustrative sketch of the different methods adopted in the construction of lake-dwellings. Hitherto lake-dwelling researches have furnished little evidence of the kind of houses erected on the artificial islands, but during last autumn a crannog was investigated in Argyllshire which has disclosed some remarkable information on this point. The discussion on lake-dwellings is fixed for Sept. 19, and as this important subject has formerly only incidentally come before the Association, the occasion promises to be most instructive to all interested in the early history of Britain. Among the other papers sent to the section is one by Mr. Romilly Allen on the "Origin and Development of Early Christian Art in Great Britain and Ireland." This paper is to be well illustrated. Indeed, this is the case with most of the archæological papers. Dr. Hildebrand is arranging illustrations of the Swedish antiquities he wishes to compare with our Anglo-Saxon ones, in groups, which are to be printed on sheets and distributed among the audience when he reads his communication.

The information contained in the above paragraphs has been furnished by request by presidents and recorders of sections; possibly further details may be forwarded in time for publication before the meeting.

The promises of exhibits of scientific apparatus, models, diagrams, and photographs in the laboratories of the University College, Nottingham, are now coming in. Scientific novelties are promised for the conversazione at the Castle.

Visitors can obtain on application the usual lists of hotels and lodgings. FRANK CLOWES.

GEORGE BROOK.

GEORGE BROOK, whose untimely decease on August 12 we have already chronicled, was born on March 17, 1857. He died, therefore, in his thirty-sixth year, apparently from the effects of heat-apoplexy, while on a visit to his wife's family near Newcastle-on-Tyne. On the fatal day he joined a shooting party on the adjacent moor; after a successful expedition and a repast in the shooting-box, he was complaining laughingly of the necessity for early rising on such occasions, when his head fell back and he expired without uttering a sound. He was buried at Benwell Church, Newcastle, where, six years previously, he was married to Fanny, second daughter of Mr. Walter Scott, of Riding Mill. He was educated at the Friends' School, Alderley Edge, and, although he afterwards studied for a couple of years under Prof. Williamson and others at the Owens College, Manchester, he may be said to have been, as a naturalist, mostly self-taught. His earlier years of active life were spent in his father's business at Huddersfield, and he turned the experience thus gained to good account in his after career. His first definite association with scientific work dates from his connection with the recently deceased Mr. J. W. Davis, of Halifax, and others, in the prosecution of biological investigation in the West Riding of Yorkshire. He was in 1884 appointed scientific assistant to the Scottish Fishery Board and lecturer on comparative embryology to the University of Edinburgh. He retired from the first-named office in 1887, leaving as a legacy a series of valuable notes and reports upon the food fishes, but the last-named one he held till death. As an embryologist, he is himself best known for his work upon the origin of the endoderm from the periblast in teleostean fishes, and although not the first to have suggested this, it must be said, in justice to his memory, that certain recent investigators have reverted to his views without according him befitting recognition. His love of experimental marine zoology, and his personal munificence in the interests of pure science, reasserted themselves in 1889, in his attempt to found a lobster hatchery and marine observatory at Loch Buie, Isle of Mull, duly noted in our pages (NATURE, vol. xlii. p. 399), and which we know to have involved him in a not inconsiderable loss. He was secretary to the Huddersfield Naturalists' Society, and to the Scottish Microscopical Society, of which he was a founder; he was for three years a vice-president of the Royal Physical Society of Edinburgh, and a member of council of the same, the Linnean Society of London, and the Royal Society of Edinburgh. He had recently joined the Zoological Society, and was but a few months ago appointed an examiner in Biology to the Royal College of Physicians, Edinburgh. In the year 1889 he rose suddenly into fame as the author of the *Challenger* Report on the Antipatharia. His preliminary paper, dealing (*Proc. R. Soc. Edin.*, vol. xvi. p. 35) with the homologies of the mesenteries in the Antipatharia and the Anthozoa, had apprised the world of the breadth of his inquiry into, and the extent of his knowledge of, this difficult and little understood group; but the preparation, within approximately a year, of that which came to be termed "one of the most praiseworthy" of all the *Challenger* reports, set a seal to his reputation, and exalted him to a foremost position among living Actinologists. In this work he elaborated his important discovery of dimorphism (in Schizopathinæ) by division of a single primitive zooid into three, instead of by specialisation of individual polypes; and at the time of his death he had well-nigh completed an important paper dealing with this and kindred subjects, for which his talented assistant, Mr. Binnie, had prepared a large series of beautiful sections and some elaborate drawings. The thorough and conscientious manner in which he had worked out the Antipatharians of the *Challenger* collection led, in 1890, to his engagement by the Trustees of the British Museum for the arrangement and cataloguing of their very large collection of stony corals; and the present month marks the publication of that which will perhaps rank as his *magnum opus*, viz., the "Catalogue of the Genus Madrepora," a quarto volume of 212 pages, with 35 beautiful plates, mostly from photographs taken by himself. This welcome treatise, which was the first of a projected series dealing with the stony corals, like most of the set to which it belongs that have appeared under Dr. Günther's direction, is, in reality, no catalogue at all, but rather a revisionary monograph, founded upon the study of rich material from world-wide localities, which must furnish a basis for succeeding inquiry into the group with which it deals. None but those who enjoyed the deceased author's personal friendship can form an adequate idea of the labour and expenditure, both of time and capital, which he bestowed upon this volume. It is the practical outcome of the last three years of his life's work. The success with which he dealt with the bewildering difficulties before him may be perhaps sufficiently gauged from its "Introduction," and to what important lines of structural investigation and conclusions the task was leading him, it is obvious from this and his last published paper "On the Affinities of the Genus Madrepora" (*Jour. Linn. Soc. Zool.* xxiv. p. 353).

The most striking features in George Brook's personality were his right living and his manly independence, his moral attributes being in every way worthy his mental ones. There can be no question that his capacity to form an independent judgment, and his great powers of organisation, under the influence of his indomitable will, formed the keystone of his successes, and placed him in a position to rise supreme above petty jealousy and the evils begotten of narrow cliquism and over-ambition. His natural inclinations were towards solid work, as will be obvious from his having originally settled down to the study of the Crustacea, but to relinquish it for that of the Corals—a choice which makes his loss a well-nigh irreparable one to British zoologists of the present generation. In addition to the many unfinished works to which we have alluded, he has left behind him at least the material for a reconsideration of the morphology of certain great veins in the Amniota, and for a detailed report upon some of the corals collected by Prof. Haddon in the Torres Strait, which had been placed in his hands. Indeed, almost his last words to the writer of this notice were expressive of a desire to "get on" with the latter. His final act, as a zoologist, was the determination of a Collemboloid (upon which group he was an authority) for his friend Prof. W. A. Herdman, with whose pioneer's work in British marine zoology he was in active sympathy. A devoted husband, an exemplary parent, a true friend, whose advice was always sound, and whose criticism was as well founded as it was frank, he passes from us in the heyday of life. His life furnishes a noble example of independent manliness, and of enthusiasm for the spread of truth and the cause of scientific advancement.

NOTES.

We learn from the *Revue Générale des Sciences* that M. d' Abbadie, late President of the Paris Academy of Sciences, has asked the Academy to accept a considerable gift in the name of his wife and himself. The donation consists of the Abbadia estate (Basses-Pyrénées), having an annual revenue o twenty thousand francs, and one hundred shares in the Bank of France, representing a capital of four hundred thousand francs and an annual income of fifteen thousand. By the deed of gift, these properties will not fall to the Academy until after the decease of the donors. Two of the principal clauses and charges of the legacy are as follows:—(1) The Academy may establish on the Abbadia estate any researches or laboratories, except those devoted to vivisection. (2) An observatory must be established at Abbadia, in which a catalogue of five hundred thousand stars can be made, the work to be completed in 1950. In order to reduce the expenses which this stipulation carries with it, the work may be confided to some religious order. The Academy has nominated a commission to examine the conditions of this munificent donation, and has expressed its deep gratitude to M. and Mme. d'Abbadia. It is not too much to say that this feeling is shared by all men of science.

The following men of science have been elected Fellows of the Reale Accademia dei Lincei:—In mathematics, Prof. L. Bianchi and Dr. G. D'Ovidio; chemistry, Dr. G. Ciamician and Prof. D. Mendelejeff; botany, Profs. E. Strassburger and N. Pringsheim; agriculture, Dr. F. Cohn. Dr. E. Bertini has been elected a correspondent in mathematics; E. Millosevich in astronomy; A. Abetti in mathematical and physical geography; and O. Mattirolo in botany.

The *Times* announces the death of Prof. M'Fadden A. Newell, Superintendent of Public Instruction of the State of Maryland, U.S.A. He was educated at Trinity College, Dublin, and the Royal College of Belfast, and went to the United States in 1848. He was Professor of Natural Science in the Baltimore City College from 1850 to 1854, and occupied the same chair in Lafayette College, Pennsylvania, from 1854 to 1864. In 1865 he was appointed President of the Normal School of the State of Maryland, succeeding, three years later, to the position of State Superintendent of Public Instruction, a post he held for a quarter of a century. In connection with Prof. Crury he published a series of text-books entitled the "Maryland Series," and his Annual Reports, in twenty-five volumes, are held in high esteem.

We regret to record the death of Father R. P. Vines, Director of Belen Observatory, Havannah.

A disastrous cyclone swept northwards along the Atlantic seaboard of the United States on August 29. At Savannah, Georgia, property to the value of millions of dollars has been destroyed, and news of great loss of life and property is reported from Brunswick, Georgia, and further south, while the town of Tybee has been completely wrecked. It is reported that the storm traced out a path marked by devastation across Georgia and South Carolina to Charlotte, in North Carolina, and thence to the east coast again to Petersburg, Virginia. The city of Savannah presents a scene of wreck and ruin surpassing even the effects of the great storm of August, 1881. For eight hours the wind rushed through the city with terrific force and swept down houses as if they were packs of cards. Nearly every house in the city has suffered some damage, and the streets have been rendered quite impassable by the wreckage.

A Reuter's telegram from New York states that a cyclone passed over that part of the Atlantic coast on August 23, in the direction of the New England States, and left its marks over a region around New York extending over an area of fully a thousand miles. A rainfall of 3·82 inches in twelve hours was measured, and is said to be the highest ever recorded by the local signal service.

The next meeting of the French Association for the Advancemence of Science will be held at Caen, with M. Mascart as president. M. E. Trélat will preside over the meeting to be held at Bordeaux in 1895.

It has been finally arranged that the Congress of the Photographic Society and Affiliated Societies shall be held on October 10, 11, and 12. All the arrangements will be completed in a few days, and a full programme will be circulated as soon as possible.

An International Exhibition of Photographic Art has been organised by the Paris Photo Club, and will be held from December 10 to the end of this year. The address of the Secretary is 40 Rue des Mathurins, Paris. An international exhibition of amateur photography will be held in the Museum of Fine Arts, Kunsthalle, Hamburg, on October 1–31.

The annual general meeting of the members of the Federated Institution of Mining Engineers will be opened on Wednesday, September 6th, in the rooms of the Philosophical Society of Glasgow. A number of papers on mining subjects will then be read, and on the two following days excursions will be made to collieries, iron and steel works, and other places of interest.

The Indiana Academy of Science has decided to make a biological survey of the State of Indiana, and Profs. L. M. Underwood, C. H. Eigenmann, and V. F. Marsters have been appointed as organisers and directors of it. The first work will be the preparation of a complete bibliography of materials bearing on the botany, zoology, and palæontology of Indiana, to be published by the Academy. When this has been done, it will be possible to discuss the fauna and flora, its extent, distribution, biological relations, and economic importance, and thus accomplish the main purpose of the survey.

Mr. J. F. James gives in *Science* a description of the "Scientific Alliance of New York," instituted at the end of last year, and having for its chief object the establishment of a centre where knowledge of what is being done in one society is conveyed to all the rest. Much is to be gained by this kind of cooperation, both by science and individual workers. Already the Alliance has been joined by the New York Academy of Science, Torrey Botanical Club, New York Microscopical Society, Linnean Society of New York, New York Mineralogical Club, New York Mathematical Society, and the New York Section of the American Chemical Society, each of these societies being represented by its president and two members upon the council of the Alliance. At the opening meeting the president deprecated the views of so-called practical men in whose eyes science "is worth only what it will bring when offered in the form of dynamos, telephones, electric-lights, dye-stuffs, mining machinery, and other merchantable wares." The need of endowment for research in the region of pure science was pointed out, reference being made to the German Universities, where the professors are expected to do original work, leaving the teaching to instructors. The second meeting was held in March, 1893, when the report of a committee, recommending the establishment of an endowment fund of 25,000 dollars for the purpose of encouraging original research, was adopted. The fund is to be known as the "John Strong Newberry Fund," and will be used for furthering researches in geology, palæontology, botany, and zoology. All information relating to it or to the Alliance can be obtained from Dr. N. L. Britton, Columbia College, New York.

THE question as to whether amber was exported from the far east to Europe is discussed by Herr A. B. Meyer in a paper read before the Isis Society of Dresden. There seems to be little doubt that some specimens now sold at Rangoon are of Baltic origin, as proved by the amount of succinic acid contained in them. But there are, on the other hand, many authorities for the early derivation of amber from India and especially Burma. There are four passages in Pliny giving India as the native country of amber, and ancient Greek authors, especially Sophocles, testify to its origin in eastern India. It would be very strange if the Phœnicians, while shipping ivory, peacock feathers, tin, jewels, and spices from "Ophir," had left behind a highly valued, abundant, striking, and easily transportable article like amber. A specimen of Burmite, as the Indian amber is now usually called, from the Indian Museum, Calcutta, gave 2 per cent. of succinic acid; another specimen, analysed by Dr. Helm, gave off none. The specimens examined by the latter "had frequently embedded in them small particles of decayed wood and bark," which recalls a passage in Archelaos, who says that the Indian amber often has pieces of pine bark adhering to it. The Indian origin of much of the amber acquired by the Mediterranean nations in ancient times appears, therefore, to be placed beyond doubt. It is, indeed, probable that Baltic amber did not become a regular article of commerce before the first century of the Christian era.

WHILST our knowledge concerning the behaviour of bacteria in animal tissues is daily receiving fresh additions, but little is known on the relatively unimportant although interesting question of their deportment in vegetable tissues. Much uncertainty exists as to whether bacteria are or are not normally present in healthy vegetable tissues, but the most recent investigations appear to show that they are absent, although they may obtain easy access through minute abrasures, and retain their vitality for a considerable time, and in some cases even multiply. This view is supported by Russell, who has recently presented an interesting dissertation to the John Hopkins University on "Bacteria in their Relation to Vegetable Tissue." A large number of examinations were made of healthy plant tissues, but in no case were bacteria isolated from them, although in wounded tissues they were frequently found. Ordinary saprophytic bacterial forms were inoculated into the healthy tissues of various plants, and were identified after several days, thus the *B. luteus* was found in large numbers in the stem of a geranium after forty days from the date of its introduction. Moreover, nearly as many bacilli were obtained 10 millimetres above the point as at the seat of inoculation, 1850 being found at the latter place, and 1764 above. In all the experiments, although the distance at which bacteria were found varied from 30-50 mm. above, in no case were they identified at more than 2-3mm. below the point of inoculation. Russell suggests that this upward distribution of the germs may be due to food materials being more abundant in the rapidly growing apex, whilst smaller resistance is offered to their passage in the less developed cellulose walls than in the more matured cell-membrane of the older tissue. Moreover, as the bacteria were definitely located in the interior of the cells, and no opening of any kind could be determined, he suggests that they have the power, by means of a ferment excreted, to work their way from cell to cell without causing a permanent rupture.

THE August number of the Journal of the Royal Horticultural Society contains several interesting papers, among which is Prof. F. W. Oliver's second report on the effects of urban fog upon cultivated plants. The report deals especially with the physiological aspect of the question, the action of fog upon plants, both by reduction of light and atmospheric impurities, being described in detail. The Rev. G. Henslow gives the results of experiments made with a view of determining the effects of growing plants under glasses of various colours. His observations show that during germination it is generally immaterial whether the seeds are subjected to light or not. In the case of a variety of larkspur, however, light was found to be positively injurious. No coloured light, or combination of lights, which was not of the quality of pure colourless daylight, gave such good results as ordinary daylight. A comparison made between plants growing under ordinary window-glass and in the open showed that the glass exercises a deletereous effect, due possibly to an excess of heat by which respiration is stimulated and assimilation reduced. It is suggested that in order to reduce "scorching" some means must be used which reduces the heat rays without lessening the whole amount of white light.

WE have received from Dr. P. Bergholz the results of the meteorological observations at Bremen for the year 1892. This station is one of considerable importance, both on account of its outfit with self-recording instruments, and even with duplicate recording instruments for some of the elements, so as to avoid any possible gap in the continuity of the records, and also on account of the long continuance of observations. The first volume of this series, for the year 1890, contained the results of observations taken since the year 1803, and we see from Dr. Hellmann's *Repertorium* that observations were taken at Bremen as early as 1795. The work contains hourly readings, and, in addition, observations arranged for three hours daily, in accordance with the international scheme, together with curves showing the diurnal range for each month and for the year; it also comprises rainfall values for four other stations, and phenological observations for eleven years; the whole forming a very complete and creditable compilation.

IN *Wiedemann's Annalen*, No. 8, Herr W. Voigt gives a further account of the progress of his attempt to determine the greatest possible number of physical constants of the same pieces of metal subjected to the least mechanical manipulation. The pieces were carefully cast and sawed into shape where necessary. It is not surprising that the constants thus obtained differ in many cases from those found in the case of drawn and rolled metals, but it seems that the object of discovering the laws of the numerical relations between the various constants render it highly desirable that the substances should be investigated in what may be called their most natural state. The constants recently dealt with are thermal dilatation, thermal pressure, and specific heats at constant pressure and volume respectively. The determination of the specific heat by the method of mixtures has led to some ingenious contrivances for minimising the errors which are apt to influence this somewhat delicate operation. The outer vessel of the Neumann "cock" for heating the body under examination was made movable instead of the inner, thus enabling it to be refilled without removing it from the stand. The loss of liquid due to the splashing produced by the metal falling into the calorimeter was avoided by throwing it into a metal cage just in contact with the liquid, which was then lowered about halfway towards the bottom. The liquid was stirred by a small turbine, and the thermometer was so arranged that it only came into contact with liquid which had ascended from the metal, and then had been drawn down through the turbine tube, thus giving a very rapid rise and gradual fall of temperature, as indicated by the thermometer. The scale was read by a small microscope provided with two wires touching the scale, the meniscus being brought midway between the two. This simple arrangemen has the effect of eliminating all parallactic errors.

THE Comité International des Poids et Mesures has issued a volume containing the proceedings of meetings held during 1892. M. L. Chappuis contributes to the volume a report of an investigation of the thermal expansion of water by the weight-thermometer method. He has made two complete determinations, one between 0° and 42°·4 C., and the other between 0° and 36°·6 C. The results show that the expansion of water from 0° to 40° is very closely given by the following expression $-0·84 - 66·573253t - 8·798939t^2 - 7·892005 \times 10^{-2}t^3, + 5·155549 \times 10^{-4}t^4$. M. C. E. Guillaume has prepared a report on the metals employed in the construction of standard scales, in which he recommends nickel as the best substance.

COLONEL WATERHOUSE has been making experiments upon the electrical action of light upon silver and its haloid compounds, and communicated his results to the Asiatic Society of Bengal in May last. His arrangement was such that one plate could be exposed to light while another with which it was in electrical connection was screened from actinic rays. From the experiments it appears that, as a general rule, sunlight has an oxidising or dissolving effect on silver, whether in acid or alkaline solutions, the exposed plates being nearly always positive, and consequently forming the anode of the voltaic couple. With solutions decomposed by silver, and forming sensitive compounds with it, the action is variable.

MR. P. JANET, in the current number of the *Journal de Physique*, describes the methods he has adopted for experiments on electric oscillations of comparatively long period, $\frac{1}{10000}$ second and thereabouts. His object more particularly is to obtain the actual form of the curves of intensity and electro-motive force, rather than to find the period and logarithmic decrement. With a modified form of interruptor of M. Mouton's he is able to read accurately to $\frac{1}{30000}$ second, or even less. A mica-condenser forms part of his arrangement, and he was incidentally led to make experiments on the "hysteresis and dielectric viscosity" of the mica, from the study of certain variations which he found in the capacity of the condenser. He sums up his results on this point thus:—"In a condenser with solid dielectrics, under the influence of rapid [electric] oscillations, there is a lagging of the charges behind the differences of potential; or, in other words, for equal differences of potential, the charges are smaller with increasing than with decreasing potentials." A new and apparently accurate method for the determination of the coefficient of self-induction is also given as a secondary result of the experiments.

IN the same journal M. R. Malagoli gives a summary of his theoretical investigations on electrolysis by alternating currents, the results of which agree with the experimental determinations of M. Mengarini. He concludes that the necessary and sufficient condition under which electrolysis by alternating currents is possible, is that the quantity of electricity passing through the voltameter during a single alternation of the current must be at least twice that which is necessary for the production of the maximum polarisation of the voltameter. Electrolytic production ceases when these two quantities become equal, and the amount of the electrolyte decomposed is proportional to their difference.

AT the meeting of the Paris Academy of Sciences on August 14, MM. Delahaye and Boutille showed an ingenious fire-alarm. A hollow ball of aluminium, 15 to 20 mm. in diameter, is supported at one end of an arm, with a counterpoise at the other end, the whole being in equilibrium at the ordinary temperature and pressure of the air. The apparatus is purposely made not sensitive enough to show the ordinary natural changes of pressure, but if the specific gravity of the air becomes diminished considerably, either from a rise of temperature or an admixture of coal gas in sufficient quantity to become explosive, the balance is destroyed, and the ball in falling completes an electric circuit by which an alarm bell is set ringing until the normal state of affairs is again established.

SIR CHARLES TODD has issued a report on the rainfall in South Australia and the northern territory during 1892, with the weather characteristics of each month.

GUSTAV FISCHER, of Jena, has recently published second and revised editions of two well-known books—Prof. E. Strasburger's "Kleine Botanische Practicum," and Prof. Richard Hertwig's "Lehrbuch der Zoologie."

MESSRS. CROSBY LOCKWOOD AND SON will publish in September a comprehensive handbook on "Practical Building Construction," by Mr. J. P. Allen, lecturer at the Durham College of Science, Newcastle-on-Tyne. The work will be illustrated by about 1,000 diagrams.

WITH reference to the article on the "Position of Scientific Experts" in our issue of the 17th inst. a correspondent informs us that for some years it has been legal for a judge to select an expert to report to the Court upon a particular matter in dispute, and this practice is occasionally followed. The mode of selection and of appointment, and the status of the official English expert, are therefore almost identical with those of his German equivalent.

THE Isle of Man Natural History and Antiquarian Society visited the Marine Biological Station at Port Erin on August 14, and Prof. Herdman, F.R.S., the director of the station, gave the members an address upon the objects and methods of marine biology. We understand that it is intended to construct fish hatcheries at Port Erin, and to wall in several of the creeks round the coast for the preservation of young fish until they reach maturity.

AN "Electrical Engineer's Price-Book," edited by Mr. H. J. Dowsing, has been published by Messrs. Charles Griffin and Co. It contains a large amount of information on the commercial aspect of electrical work, and should be of great assistance, not only to electrical engineers, but also to borough engineers, architects, railway contractors, and local authorities who desire to be informed upon matters connected with electrical installations.

BRAZIL produces, on the average, about 360,000 tons of coffee per annum, that is, about four-fifths of the whole amount consumed in the world. Since the State of Sao Paulo alone produces one-half of this quantity, an illustrated pamphlet by Señor Adolpho A. Pinto, one of the Commissioners of the State at the World's Columbian Exposition, would be expected to contain an accurate account of coffee cultivation. The little pamphlet justifies the expectation. Every one interested in coffee-growing in general, and in Sao Paulo in particular, will find it well worth reading.

IT was generally admitted by those competent to judge that the display of scientific instruments at the Paris Exposition of 1889 was inferior to that of 1878. There were, however, a few striking exhibits scattered in different classes in an unaccountable manner. Mr. A. Lawrence Rotch was appointed to report upon the meteorological instruments at the exhibition, and though there was a difficulty in comparing objects in the same class, owing to their being distributed over an immense area, it was satisfactorily overcome. Meteorologists will be glad to know that Mr. Rotch's report has been extracted from the second volume of the Reports of the U.S. Commissioners to the Universal Exposition at Paris, and is now issued separately.

THE report on the operations of the Department of Land Records and Agriculture, Madras Presidency, for the official year 1891–92 has been received. From it we learn that experiments made by the Madras railway companies in the use of eucalyptus leaves to prevent incrustation in locomotive boilers have turned out very satisfactory, and are therefore being continued. The chief feature of the year was the comparative immunity from serious disease which the cattle enjoyed. The total reported losses (87,000) were only fifty-eight per cent. of the average losses, and fifteen per cent. less than in 1890–91. The losses from snake-bite decreased from 2,698 to 1,751, and the decrease was spread over the whole Presidency, except Ganjam and Vizagapatam. Losses by wild animals also decreased by 345 head. No reason is given to account for this singular reduction.

THE Royal Society of Tasmania issued in June last the reports of its proceedings in 1892, and the volume has just reached us. Among other papers printed in full occurs one by Mr. G. M. Thomson on Tasmanian crustacea, with descriptions of new species, and another on new species of Tasmanian araneæ, by Mr. A. T. Urquhart. The Rev. F. R. M. Wilson contributes a paper on the climate of Eastern Tasmania, indicated by its lichen flora, in which he gives facts which "suggest to the medical faculty what probably their experience has already proved, that the climate of East Gippsland and the eastern coast of Tasmania must be pre-eminently beneficial to invalids. Lichenological observations indicate that both of these places are favoured by a much milder winter, as well as a cooler summer, than the other parts of their respective colonies." Mr. Wilson also gives a description of Tasmanian lichens, and Mr. John Shirley a list of those now known.

DR. D. S. JORDAN showed in 1889 that, in every case where the waters of Yellowstone Park were destitute of fish, the cause was topographical, that is to say, there was some physical barrier to the entrance of fishes from below. This being so, it seemed possible to stock these waters permanently with game-fish, so the U.S. Commissioner of Fish and Fisheries sent Prof. S. A. Forbes to Yellowstone Park in 1890 to investigate the variety and abundance of the lower animal life of the fishless waters, since upon this the fishes introduced would chiefly have to depend for food. Prof. Forbes has prepared his "Preliminary Report on the Aquatic Invertebrata Fauna of the Yellowstone National Park, Wyoming, and of the Flathead Region of Montana." In it he presents a summary review of the invertebrate life of the waters of Wyoming and Montana in the mid-summer season, with descriptions and determinations of such new or particularly abundant kinds as have thus far been made out. A detailed discussion of the results will be published as soon as the mass of material collected during the expeditions has been examined.

THE organo-metallic compounds of magnesium form the subject of a communication to the current number of *Liebig's Annalen* by Dr. Fleck of Tübingen. The di-methyl, di-ethyl and di-propyl compounds of magnesium were obtained by Dr. Löhr in the same laboratory in 1890. Dr. Fleck has continued the work, and now describes the di-phenyl compound and gives further details concerning the mode of preparation and properties of the fatty alkyls above mentioned. The magnesium alkyls are of a somewhat similar nature to the well-known zinc methide and ethide. They differ, however, in the nature of certain of their reactions, and their chemical activity is considerably superior to that of the zinc alkyls, which have hitherto been regarded as exceptionally active substances. Not only are the magnesium compounds spontaneously inflammable in the air, but the methyl compound was described by Dr. Löhr as igniting spontaneously and burning in a very beautiful manner in carbon dioxide gas, being capable of extracting the oxygen from its combination with carbon. The three fatty alkyls are best prepared by the action of the alkyl iodides upon magnesium amalgam. When an attempt, however, is made to prepare the diphenyl compound by heating in a closed and previously exhausted tube a quantity of magnesium amalgam and brombenzene, instead of obtaining magnesium diphenyl decomposition occurs, and the resulting product is merely a mixture of bromides of magnesium and mercury with diphenyl itself $(C_6H_5)_2$. Dr. Fleck has at last succeeded in preparing magnesium diphenyl by heating a mixture of magnesium filings and mercury diphenyl, $Hg(C_6H_5)_2$, within a narrow range of temperature. About ten grams of mercury diphenyl and a little more than the calculated quantity of magnesium in fine powder are placed in a tube of soft glass, which is then exhausted by means of the air pump and sealed. Upon heating the tube and contents to 200 a violent reaction suddenly occurs, with production of a voluminous white mass occupying at least three times the space of the original mixture. Above 210° this white substance commences to carbonise, so that the tube is maintained for four or five hours at a temperature of 200—210°, not exceeding the latter limit. The product is spontaneously inflammable in air, so that it is necessary to open the tube under benzene. Any excess of mercury diphenyl is dissolved out by warming with benzene over a water bath, the residue is then treated with a mixture of ether and benzene, in which alone of all the organic solvents tested magnesium diphenyl is soluble; upon decantation from the residual amalgam and evaporation of the clear liquid in a stream of nitrogen, pure magnesium diphenyl is obtained as a grayish-white solid. Analyses of the product agree with the formula $Mg(C_6H_5)_2$.

MAGNESIUM diphenyl, like the dimethyl, diethyl and dipropyl compounds, reacts in a most violent manner with water. Even when the substance is first covered with ether, and then small pieces of ice are slowly added, the reaction still occurs almost explosively. Magnesium hydrate and benzene are the products of the reaction as indicated by the equation

$$Mg(C_6H_5)_2 + 2H_2O = Mg(OH)_2 + 2C_6H_6.$$

Magnesium diphenyl is consequently extremely hygroscopic, attracting moisture from the air with great rapidity when covered with a layer of benzene. When freely exposed to the air it at once burns to magnesium oxide and a carbonaceous mass. If, however, the compound is covered with benzene and exposed to perfectly dry air for some days, an oxy-compound, $Mg(OC_6H_5)_2$ is formed as a brown solid. Bromine reacts with great energy to form bromides of magnesium and phenyl, even when largely diluted with ether, and so does not form an intermediate compound,

$$\mathrm{Mg}\Big\langle{}^{\mathrm{Br}}_{\mathrm{C_6H_5}}$$

corresponding to the well-known zinc iodo-ethide,

$$\mathrm{Zn}\Big\langle{}^{\mathrm{I}}_{\mathrm{C_2H_5}}$$

Indeed, this incapability of forming mixed halogen alkyls, owing to greater activity, is one of the most characteristic distinctions between the magnesium and the zinc alkyls generally. Benzal chloride, $C_6H_5.CHCl_2$, reacts with magnesium diphenyl in an interesting manner, forming without extraneous application of heat triphenylmethane, $(C_6H_5)_3CH$, and magnesium chloride.

Notes from the Marine Biological Station, Plymouth.—The *Actinotrocha* larva of *Phoronis* has now made its appearance in the floating fauna. The Radiolaria mentioned last week, though still present, have become much less numerous; the tow-nets have this week been crowded with *Rhizoselenia.* The Siphonophore *Muggiæa atlantica* is abundant, and the medusæ *Saphenia mirabilis* and *Amphinema Titania*, with swarms of small *Obeliæ*, have also been observed. The Nauplii of *Sacculina* are plentiful, and among Mollusca the larvæ of *Ægirus punctilucens* and the larva *Cirropteron semilunare* of M. Sars (possessing a four-lobed velum) have been observed. The Polyclad *Leptoplana tremellaris* is now breeding; and young metamorphosed specimens of the Opisthobranch *Oscanius membranaceus* have been taken with the dredge on the bottom.

The additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus*) from India, presented by Mrs. H. Leavitt: a Blau-bok (*Cephalophus pygmæus*) from South Africa, presented by Mr. J. E. Matcham; a Yellow Baboon (*Cynocephalus babouin*) from West Africa, a Banded Gymnogene (*Polyboroides typicus*) from East Africa, a White-necked Stork (*Dissura episcopus*) from East Africa, presented by Mr. Thomas E. Remington; a European Tree Frog (*Hyla. arborea*) from Europe, two Fire-bellied Toads (*Bombinator igneus*) from Europe, and a Spotted Salamander (*Salamandra maculosa*) from Europe, presented by Mr. Hood; eleven Garden Dormice (*Myoscus quercinus*) from Spain, forty-eight Glossy Ibises (*Plegadis falcinellus*) from Spain, and four Marbled Ducks (*Anas angustirostris*) from Spain, presented by Lord Lilford, F.Z.S.; a Rose-crested Cockatoo (*Cacatua moluccensis*) from Moluccas, presented by Lady Sudeley; two Ypecaha Rails (*Aramides ypecatra*) from South America, presented by Mr. F. H. Chalk, a Boa (*Boa constrictor*) from South America, and two Great Bustards (*Otis tarda*) from Spain, deposited; and a Wapiti Deer (*Cervus canadensis*) born in the Menagerie.

OUR ASTRONOMICAL COLUMN.

Honorary Distinctions.—From the current number of *L'Astronomie* we gather that M. Janssen, director of the Observatory of Meudon, has been made a Commander of the Legion of Honour. Messrs. Callandreau and Bigourdan, assistant-astronomers at the Paris Observatory, have received the distinctions of Officers of Public Instruction, and MM. Camille Flammarion and Jordan and Hermite, of the Institute, have received from the King of Greece the Cross of the Commander of the Order of the Saviour.

A Meteor.—An observer, writing to us from Westgate-on-Sea, gives the following account of a meteor seen there on the evening of August 27:—"At about 8.40 p.m. I saw a very brilliant meteor here. The trail, as far as I could judge, must have commenced somewhere about the star β Sagittæ, but the most brilliant part of it was accurately noted as lying between two points, one being half-way between α and γ Aquilæ and the other being about a third of the distance (from η) between η and δ of the same constellation. The meteor may be described as "rapid," and its direction of motion was south. The most striking feature of this observation was the length of time (about six minutes) the trail remained visible in the heavens, and its subsequent change of shape. At first it appeared of a bluish-white colour and was very bright, its path describing practically a straight line; but about four minutes later it had dimmed very considerably (the same colour being maintained), but the trail was no longer straight but distinctly *wavy*, giving one the idea that the meteoritic dust particles must have encountered some air currents travelling at right angles to its length."

A Bequest to Astronomy.—By the will of Mr. Arthur Leake, late of Ashby, Ross, Tasmania, a sum of £10,000 was put by for the purpose of founding a school for the practical teaching of astronomy in one of the Australian universities, colleges, or leading schools. It was stipulated that a part of such teaching should consist of lectures illustrated with diagrams and instruments, and the sum of £3000 could be spent in purchasing the necessary equipment. From the proceedings of the Royal Society of Tasmania (issued June, 1893) it appears that there is a little difficulty in determining the best means of using the bequest. Mr. H. C. Russell, F.R.S., C.M.G., has drawn up a scheme for the proposed school which has much to commend it. He points out that Hobart offers special advantages of climate and position for the Leake Observatory, and suggests that £1800 should be spent in purchasing a photographic astronomical telescope, to be used for work in connection with the photographic chart. It is proposed that the University of Tasmania shall establish a school of astronomy and the observatory, and that the lecturer in mathematics and physics shall also teach astronomy, and have general control and direction of the observatory, for which he should be paid from the Leake fund £100 per annum in addition to his salary from the university. An observatory assistant is provided in the scheme with a salary of £200 per annum. The sum of £50 a year is set down for photographic plates, chemicals, &c., bringing the total annual expenditure up to £350, which is the interest on £7000 from the Leake estate. When Mr. Russell's paper was read, in August, 1892, an opinion was expressed that it was unnecessary to "import an astronomical expert in order to give the instruction in astronomy, and to superintend the observatory," and that the duties of the observer might be combined with those of the Government meteorologist. With this feeling the following resolution was passed:—"The Royal Society of Tasmania having placed itself in communication with the Council of the University with the view of formulating a scheme for securing the benefit of the Leake bequest to the colony of Tasmania, the Premier be requested to refrain from making any permanent appointment to the office of meteorologist pending the result of such conference."

GEOGRAPHICAL NOTES.

Dr. Nansen has telegraphed from Yugor Strait, at the entrance to the Kara Sea, on August 3, the message reaching the Vardö telegraph office on August 23. A good voyage had been made to Nova Zembla, the only unpleasant episodes being the occurrence of fogs and contrary winds. On the 27th ice was encountered in lat. 69° 50′ N., long. 50° E., about ten miles north-east of the Island of Kolgueff. Dr. Nansen forced his way through the ice, the *Fram* proving a splendid ship for the purpose, and reached Yugor Strait on the 29th, making a run of 250 miles in two days. The coal-ship, which was to have been waiting at Yugor Strait, had not arrived, but having sufficient coal on board Dr. Nansen intended to sail into the Kara Sea on August 3, rather than risk delay by waiting. He took on board "thirty-four splendid sledge-dogs." Little ice was reported in the southern part of the Kara Sea, a southerly wind having driven the pack northward. If the ice does not turn out worse than reported, Nansen hoped to reach the New Siberian Islands before the end of August, and if he does so he considers success almost certain. The *Fram* will touch at the Olonetz River, near the Lena delta, if there is time, and send farther news.

The geography of South America has recently been receiving great attention from German travellers and officials in the various South American republics. In a recent number of *Petermann's Mitteilungen*, Richard Payer describes a journey from Lima across the Andes and down the valley of the Ucayali to the Amazon. In the course of it he visited an interesting Tyrolese colony at Pozuzo, which he found in the course of extinction, after thirty years' hard struggle on the part of the colonists to maintain a footing in their remote and isolated settlement. Dr. Brakebusch has from time to time published portions of the material he has been collecting for an exhaustive account of the physical geography of the Argentine. He divides the country from the crest of the Andes to the valley of the Parana into successive zones—snowy summits and cliffs, high-level sand-dunes formed from glacial débris, screes, alpine pastures, low-level sand-dunes, salt flats, forests, and pampas.

Dr. Hettner has been at work on the Andes of Colombia, and Dr. Theodore Wolf has published a magnificent monograph (in Spanish) on the geography and geology of Ecuador, accompanied by the best map yet produced of the country. Dr. Tippenhauer has written a fine work on the physical geography of Haiti, and many other papers by German geographers have appeared within the last few months.

SIR WILLIAM MACGREGOR, for the British Government, and the officers of the Dutch war-vessel *Java*, have rectified the frontier between British and Dutch New Guinea. The former boundary was the 141st meridian, and the new boundary, where it cuts the coast, is a stream, chosen to furnish a recognisable border-line, in 141° 1′ 40″ E. and 9° 7′ 40″ S.

ON August 6 the new ship-canal across the Isthmus of Corinth was formally opened, thus completing a plan which was projected by Periandros about 600 B.C., and actually commenced by Nero, who was, however, compelled to abandon the work, in 68 A.D. The canal is not quite four miles long, and will effect a saving of 120 miles in the passage from the Adriatic to the Ægean. Two new towns have been planned at the entrances to the canal, which will be named Poseidonia and Isthmia.

MR. F. C. SELOUS, the recognised authority on the exploration of Mashonaland, has been induced to return there at very short notice, on account of the threatening attitude of the powerful Matabele chief, Lo Bengula, and the consequent risk of interruption in the development of the country. An important work on Mashonaland, by Mr. Selous, will be published immediately.

MR. R. M. W. SWAN, who, with Mr. Theodore Bent, surveyed the ruins of Zimbabwe, is at present engaged in a systematic survey of other groups of ruins in South Africa, and he reports the discovery of a temple on the Limpopo, "oriented" to the setting sun at the solstice.

MR. W. H. COZENS HARDY, the Oxford geographical scholar, is now engaged in carrying out his explorations in Eastern Montenegro, one of the least known parts of Europe. The work of his predecessor, Mr. Grundy, on the Battlefield of Platæa, is on the point of publication as a supplementary paper of the Royal Geographical Society.

THE BEAVER CREEK METEORITE.

SOME of the readers of NATURE will no doubt be interested in a short account of a meteoric fall which occurred recently in British Columbia, and was noted in these columns on August 10. For the circumstances in connection with the fall, and the finding of fragments of the meteorite, I am indebted to Mr. James Hislop—a former student of this University, and a most trustworthy observer—and also to a letter by Mr. E. L. McNair in the *Spokane Review* of June 2.

Both gentlemen were members of a party of engineers engaged upon a survey for the Nelson and Fort Sheppard Railway Company on Beaver Creek, about eleven miles north and five miles east of where the Columbia crosses the international boundary line. About four o'clock on the afternoon of May 26 a series of sharp reports was heard, following one another in quick succession, and apparently occupying in all about half a minute. The first report was quite loud and sharp, and each succeeding one less so, as if coming from a greater distance. Following the reports was a whizzing sound, such as might be supposed to be produced by a body moving rapidly through the air.

At the time of the "explosion" a man named Gerling was walking along the Beaver Creek trail. At first he thought that the noise was thunder, but the whizzing sound puzzled him, and on looking upward to see if he could tell whence it came, it grew louder and louder until a stone struck the ground not far from where he stood. He searched for it, but without success, as the place was thickly overgrown with bushes.

Some distance from this a fragment fell within fifty feet of a man named Edward McLeod. It buried itself in the earth, but was dug out, and found to weigh four or five pounds. On the following day (May 27), in the course of his topographical work, Mr. Hislop came upon a freshly-made hole in the ground into which the loose earth had fallen, and on following it down to a depth of three feet from the surface a portion of the meteorite weighing about twenty-five pounds was discovered. The hole made an angle of 58° with the horizontal, and its course showed that the mass had come in a direction S. 60° E. (true meridian), The writer is indebted to Mr. Hislop for a portion of this mas[s] and a preliminary examination fully establishes its meteori[c] character.

The fresh fracture is light grey in colour and harsh to th[e] touch, the crust being brown and dull. The chondritic characte[r] is distinctly seen without a lens, though the "chondra" ar[e] mostly under a millimetre in diameter. Examination of a thi[n] section with the microscope showed the presence of olivin[e,] enstatite, iron, troilite, and chromite (?). The iron is present i[n] the form of little shining grains and strings. On treatment wit[h] hydrochloric acid the powder gelatinises readily (olivine, an[d] evolves hydrogen sulphide. By means of an ordinary hors[e]shoe magnet some of the powder was separated into a magnet[ic] and a non-magnetic portion. The former amounted to abo[ut] 23·5 per cent. of the whole, and consisted mainly of nickel-iro[n,] which, however, carried with it a portion of the other co[n]stituents.

A partial analysis of the magnetic material gave:—

Iron	78·72
Nickel (including cobalt)	6·87
Insoluble in hydrochloric acid	10·04
Soluble silica	1·46
Magnesia, &c., by difference	2·91
	100·00

If all the iron and nickel present be regarded as nickel iro[n,] the percentage of nickel (with cobalt) is 8·73. No doubt, ho[w]ever, a little of the iron was derived from olivine and possib[ly] from troilite.

The writer hopes to publish before long the results of a le[ss] hurried and more detailed examination of the specimen in [his] possession.

B. J. HARRINGTON.

SPANGOLITE, A REMARKABLE CORNISH MINERAL.

AMONG the valuable Cornish minerals from the Willia[ms] collection which have recently been acquired by t[he] trustees of the British Museum[1] is one specimen which deser[ves] immediate notice, since it proves to be a recently discover[ed] mineral of which only one other example is known to ex[ist,] and that from a foreign country.

The mineral belongs to the fine series of copper ores from [the] St. Day mines, which are chiefly arsenates and phosphates, a[nd] among these, while it exceeds the remainder in scientific [in]terest, it is inferior to none in beauty.

The specimen, about the size of a hen's egg, consists o[f] granular gossany quartz carrying on both sides a little mas[s of] cuprite, which is covered and replaced by greenish alterat[ion] products—chrysocolla, malachite, liroconite, and clinocla[se,] together with a little chessylite; especially conspicuous be[ing] the bright green crystals of liroconite and indigo-blue group[s of] clinoclase.

But among these, dispersed upon both sides of the specim[en,] are numerous brilliant and translucent crystals of a c[...] emerald-green colour, which at once strike the eye as so[me]thing unusual. Their form is a hexagonal prism terminated [by] an acute hexagonal pyramid having the apex truncated b[y a] single bright plane; and one cannot call to mind any ot[her] mineral having precisely this habit.

A minute group of crystals was detached and examined [by] Mr. Prior and myself with the following result:—The min[eral] belongs to the rhombohedral system, the pyramid angle be[ing] 53° 7′; it has a perfect basal cleavage; it is uniaxial, the b[i]fringence being strong and negative; the specific gravity, de[ter]mined by suspending a fragment in solution of cadmium bo[ro]tungstate (Rohrbach's solution), is 3·07; it is insoluble in wa[ter,] but readily soluble in acids; and is found to be a hydrated [sul]phate and chloride of copper and aluminium. This indic[ates] a very remarkable and unusual composition, but the prese[nce] of both aluminium and chlorine is quite unmistakable.

In all the above characters the substance is identical w[ith] spangolite, a new copper mineral which was described by [...] S. L. Penfield in 1890 (*American Journal of Science*, [...] p. 370).

The resemblance between the two specimens extends e[ven] to the circumstances of their discovery; the original spang[olite]

[1] NATURE, vol. xlviii. p. 357.

was found in a collection of minerals where it had attracted no attention until Mr. Spang obtained the specimen and brought it to the notice of Mr. Penfield; the present specimen has probably remained unnoticed in the Cornish collection at Caerhays for a large number of years.

The local collection from which the American specimen was obtained belonged to a man living near Tombstone, Arizona, who had gathered together his minerals within a radius of about two hundred miles, so that although the exact locality and mode of occurrence are unknown, it is almost impossible that this specimen can be also Cornish.

From the typical character and appearance of the associated clinoclase and liroconite the British Museum specimen (although no label or history is attached to it) can be pronounced to be without the least doubt from the St. Day district, near Redruth, in Cornwall.

The American specimen is described as "a rounded mass of impure cuprite which was mostly covered with hexagonal crystals of spangolite, associated with a few crystals of azurite and some slender prismatic crystals of a copper mineral containing chlorine, probably atacamite"; it therefore differs considerably from the Cornish specimen as regards the associated minerals.

The only apparent difference between the spangolite on the two specimens is in the habit of the crystals, which in the American mineral are short prisms with bevilled edges and a large base, quite unlike the acute Cornish pyramids in aspect. The pyramid angle found by Penfield is 53° 11½′, and the specific gravity 3·141. Penfield further made some interesting observations concerning the etched figures of spangolite; he describes and figures certain beautiful triangular markings produced upon the basal plane by the solvent action of very dilute acids. We have found that precisely the same characteristic figures are engraved upon a cleavage flake of the Cornish mineral when it is immersed for a few minutes in dilute acid.

The American crystals attain considerable dimensions; the largest had a length of 5½ mm. and a breadth of 8 mm., and by sacrificing half the specimen Penfield was able to obtain more than 3 grams (!) of pure material for analysis. The Cornish crystals are not more than 2½ mm. in length and ¾ mm. in breadth, and it will be difficult to obtain sufficient material for a complete analysis, unless other specimens can be found. This is unfortunate, for the composition is so peculiar that, although Penfield's analysis is without doubt perfectly reliable, it would have been interesting to confirm his formula from a new locality. The preliminary examination serves, however, not only to establish the identity of the mineral, but also to prove the most important point—that the aluminium and chlorine are essential constituents.

The formula deduced by Penfield is

$$Cu_6AlClSO_{10}.9H_2O.$$

in which, as he remarks, the aluminium is just sufficient to satisfy the quantivalence of the total acids, thus:—

$$(AlCl)SO_4.6Cu(HO)_2.3H_2O.$$

The mineral is therefore closely related to connellite, a very rare sulphate and chloride of copper also found in the St. Day district, which, moreover, it somewhat resembles in appearance, having the same black colour when viewed by reflected light alone. The colour by transmitted light, together with the perfect basal cleavage are, however, sufficient to distinguish spangolite from all known minerals; further, the basal plane is as common on spangolite as it is rare on connellite.

It is to be hoped that search will be made among old collections and upon copper ores from St. Day for further specimens of this interesting mineral. H. A. MIERS.

DESULPHURISATION OF IRON.

THE elimination of sulphur from iron and the chemical reactions, whereby sulphur, in the presence of powerful basic materials, is removed from crude iron, has recently attracted considerable attention. There are many reasons for this; pure ores have become comparatively scarce, and to some extent the same may be said of the fuel or coke used in the process of smelting. And even if this be not strictly applicable in all districts where the manufacture of iron is pursued, yet it cannot be gainsaid that excessive competition, with concurrent low prices, have had an influence in rendering the strictest economy in the manufacture absolutely necessary, and thus in a measure preventing the free use of pure high-priced materials.

I may even go further and assert that under favourable conditions, that is, as regards general manufacturing expenses, localisation of plant, &c., the cost of pure good materials, unquestionably suitable for smelting purposes, may become quite prohibitive. In numerous instances manufacturers have therefore been compelled to use cheaper fuel and ores falling within the margin of economic working. At this point, however, other fresh difficulties have to be combated; for when the problem of the production of iron and steel at a reasonable rate has been solved, it is too often found that the metal thus manufactured fails to meet demanded requirements. It is often the case that when iron thus produced is converted into steel, a want of uniformity in quality can be distinctly traced throughout the manufactured product. Though the steel can hardly be termed bad, nevertheless, as a general rule, it compares unfavourably with the metal smelted from purer ores with good fuel or coke.

The causes tending to the production of this inferior metal or steel are well known, and may be summed up in a few words. (1) The use of inferior coke in the blast furnace is at once a cause of deterioration, for the heat is less intense, and this tends to the production of a low grade iron.

(2) It is evident that the use of inferior cheaper ore causes a further deterioration in quality, whilst any attempt to remedy this by lightening the furnace burden of ore—in other words, using a greater quantity of coke—is, in many instances, counterbalanced by the inevitable additional impurities charged, *i.e.* sulphur and phosphorus, and other additional incombustible matter or ash.

It follows as a matter of course that the blast furnace can only work in this direction within a very narrow limit, either plus or minus attempts to limit the quantity of coke used resulting, as before said, in the production of low grade iron. On the other hand, an increased quantity of fuel with the use of inferior ore increases the total amount of impurities.

The working limit on either side is soon reached, and any further attempts at improvement either way become simply useless. Certainly, very highly heated air or blast might to some extent obviate some of the difficulties, but as in modern practice this is already thoroughly carried out, the employment of a higher temperature of blast would appear to be practically impossible, and it is very likely that the attempted use of abnormally heated blast or air would entail other serious practical difficulties.

This is the common experience of those engaged in the manufacture of iron and steel, more especially in blast furnace smelting operations, showing that under the unfavourable conditions before mentioned, it is practically impossible to produce a high-class iron containing the minimum percentage of sulphur and phosphorus together, with the requisite quantities of silicon and graphite necessary to ensure the production of good steel.

Thanks to the painstaking investigations of Mr. Stead, we can now form a tolerably clear idea of the reactions involved in the elimination of sulphur, both in the blast furnace and by other or secondary processes. These may be broadly summed up in his statement that sulphide of iron is dissolved out of the metal in the first instance by free or loosely attached lime, in a highly reducing atmosphere at a high temperature, as by the Saniter process, where lime dissolved in calcium chloride is used; and in the blast furnace by the excess of lime in solution in the slag, or even a mixture of ordinary blast furnace slag and lime, the latter being capable of eliminating sulphur from iron, and may be substituted for Saniter's mixture. The results, however, so far as can be ascertained, are somewhat irregular with either of these methods. Finally, there can be little doubt, as suggested by Mr. Stead, that if lime alone is brought into intimate contact with molten iron by suitable mechanical appliances, neither calcium chloride nor slag is needed, these having little or no direct chemical action on the metal, but merely forming vehicles for the transmission and mixing of the lime with the iron, and consequent washing out of solution of iron sulphide, followed by the subsequent conversion into calcium sulphide and iron oxide.

"The reactions in this process are, however, exceedingly complex, and there are changes which occur of which we know little or nothing. It is, however, my opinion that the sulphide of iron is dissolved out of the metal in the first instance by the free or loosely-attached dissolved lime; but I do not care at present, without more extended investigations, to hazard an opinion as to what the subsequent reactions may be."[1] Subject to what may be said of particular instances or occasional exceptions, the statements made by me as to the result of many years' observation and experiment of others and myself are on the whole practically accepted. Probably Mr. Stead is correct when he assumes that the dissolved iron sulphide is resolved into calcium sulphide, and iron oxide, as by the Saniter process, or in the blast furnace, by the excess of lime in solution in the slag.

In this connection, as regards the blast furnace, heat plays a double part, firstly for the intensification of the chemical affinity of sulphur for the alkaline base (lime, of the slag; secondly, for the adequate liquefaction of this highly basic slag, overcharged with lime and requiring a high temperature for its perfect fusion, which otherwise would remain in and clog up the blast furnace, thus obviously checking the proper working of the furnace and the uniform descent of the materials charged above.

Phosphorus is apparently not eliminated in sensible quantities under the above conditions. Practically the whole is retained and passes into the pig iron. Blast furnace slags are, however, never quite free from phosphorus, and some species of the latter contain sensible quantities, the amount depending on the excess of phosphorus present in the ores, and the working conditions. Usually such slags contain an excess of iron oxide as compared with ordinary grey iron slags, the latter being generally free from iron oxide or, at any rate, the amount does not exceed ½ per cent. in good slag.

Metallurgical experts have for some time been engaged in devising methods for the removal of sulphur. It is needless here to recapitulate in detail the very many processes tried by them, and for the most part abandoned. All are based on the use, in one way or another, of alkaline or basic materials. However, the experience thus acquired seems to have been utilised, and has led to valuable tangible results, for of late several processes have been worked out with some degree of success, but in our opinion there is still room for improvements, both in cost and general efficiency. In addition, the time and trouble involved in these processes ("which may be classified as methods of secondary purification," *i.e.* methods by which the iron is to some extent freed from sulphur after its production in the blast furnace) are important items seriously impeding further progress. It really seems that the proposed methods of secondary purification may ultimately prove too tedious and expensive, the limit betwixt loss or gain being just now very small. Recognising this, attempts have been made to cheapen the processes, all, however, based on the use of alkaline or basic material, but so far it appears the results are somewhat uncertain.

Mr. Saniter's lime and calcium chloride method, "one of the first recently propo ed and tried," has been worked, as the writer can testify, with some success, but the costs, by general consent, are considered somewhat heavy. It is only fair to say that the inventor is not of this opinion, and he quotes reasons to the contrary which should be well weighed before a final opinion is held as to the merits of this process. Secondary processes must from their very nature be costly and troublesome when dealing with the production of thousands of tons of metal continuously flowing from the blast furnace throughout the year.

The earlier attempts to purify crude iron from sulphur, &c., merely paved the way for recent developments, and, on the whole, merely suffice to prove that alkaline or basic substances only can effectively be used. It is now generally admitted that lime is the only base which can be applied with anything approaching economic results, and the methods now being practised have resolved themselves into endeavours to use this reagent efficiently and economically. Manganese as another reagent is an effective desulphuriser, but this requires to be separately investigated.

Lime is, and always has been, used in the blast furnace for the elimination of sulphur from iron; and it is well known that a non-sulphury pig-iron cannot be manufactured unless an excess of lime be charged into the furnace over and above the lime required for the formation of a fluid slag or lime silicate. It is evident, however, that the use is limited owing to the infusibility of the basic slags formed. These are facts which need no further comment, as they are universally acknowledged on all sides. If some modification could be introduced into ordinary blast furnace charging whereby this infusible slag containing an excess of lime could be continuously cleared out of the furnace, we should have at our command a continuous *direct* method of eliminating sulphur from iron at a minimum expenditure, and at a great saving in the time and labour involved in the processes of purification.

JOHN PARRY.

[1] Stead, Iron and Steel Institute.

THE METEOROLOGICAL OBSERVATORY ON BEN NEVIS.

THE Directors of the Ben Nevis Meteorological Observatory have prepared a guide book which will be of great use to the tourist who desires to scale the top of the Ben and feast his eyes upon the crag and mist beneath, and also to the large number of people interested in meteorology. By the kindness of the publishers (Messrs. John Menzies and Co., Edinburgh and Glasgow) we are able to give three illustrations of the Observatory, with an account of its foundation and the work carried on there. For many years it has been recognised that the best means of obtaining definite information as to the vertical variation of atmospheric conditions was to establish meteorological stations differing considerably in altitude but in the same locality. In this connection we read that "in 1877 Mr. Milne Home, then Chairman of the Council of the Scottish Meteorological Society, pointed out the singular advantages of Ben Nevis as a high-level station. It is the highest mountain in the British Islands (4406 feet); its summit is, in horizontal distance, about four miles from a sea-level station at Fort William, and is situated in the track of the south-west storms from the Atlantic, which exercise such a preponderating influence on the weather of Europe, especially in autumn and winter. Its advantages are therefore unique, and observations made there have proved to be of the greatest interest and value to meteorology."

Unfortunately, though a plan of an observatory was prepared by the late Mr. Thomas Stevenson in 1879, for the Scottish Meteorological Society, the work could not be proceeded with for want of the necessary funds. From June to October, 1881, however, Mr. Clement L. Wragge made observations at the summit simultaneously with Mrs. Wragge at Fort William, and an elaborate series of simultaneous observations at different heights on the mountain were successfully made in the two following years. The discussion of these observations led to very important results, and was the means of exciting the interest in the public mind essential to the obtaining of subscriptions. An appeal for funds to enable an observing station to be erected was promptly responded to, a sum of £4,000 being soon collected. A feu of an acre of land was obtained on the top of the mountain from Mrs. Cameron Campbell, of Monzie, and upon it an observatory was erected from plans by Mr. Sydney Mitchell. "The observatory was opened by Mrs. Cameron Campbell on October 17, 1883. Observations were begun in the following month, and have been carried on ever since. At the same time a sea-level station was opened at the public school, Fort William, under charge of Mr. C. Livingston, where comparison readings were taken five times a day with great punctuality and accuracy. But a few years showed the necessity of having a continuous record at sea-level as well as on the summit, and in 1889 the directors resolved to carry out the original plan which want of funds had hitherto prevented, and set up a low-level observatory. Aided by a grant from the Edinburgh Exhibition of 1886 and contributions from the public, they were able to erect a suitable building close to sea-level, on ground feued from Mr. Cameron, of Lochiel, in the beginning of 1890. The Meteorological Council of London equipped this station with self-recording instruments, and increased their annual grant to the directors from £100 to £350. Observations began in the middle of July, 1890, and since then there has been a continuous record of barometric pressure, temperature, humidity, rainfall, &c., by day and by night, both on the summit of Ben Nevis and at sea-level. The distance between the high and low-level observatories is only 4⅔ miles, and their heights above sea-level respectively 4407 and 42 feet. Mr. Livingston also continued his observations for a year after the commencement of the low-level observatory, so that there might be a satisfactory comparison of the two sea-level stations. The telegraph wire from the summit has been extended to the low-level observatory, and the observers can communicate with each other at any time, and reports from both stations are sent daily to the newspapers. The high and low-level stations are worked as one observatory, the observers being interchangeable, and the low-level serves also as a depôt for stores, &c., which are carried up during the summer to the top." The original buildings on the hill-top were found too small for the double purpose of carrying a set of anemometers and of providing a convenient exit when the winter snows have closed the ordinary doorway.

FIG. 1.—The Observatory in Summ

FIG. 2.—The Observatory in Winter.

satisfactorily carrying on the work of the observatory, so in the summer of 1884 large additions were made, the most important being the erection of a tower about thirty feet high, which serves

The Winds of Ben Nevis.

In addition to the routine work, other observations and researches have been carried on by the observers on Ben Nevis.

"An exhaustive examination of the 'Winds of Ben Nevis' has been made by Messrs. Omond and Rankin, and the results published in the 'Transactions of the Royal Society of Edinburgh.' It is shown that while the sea-level winds in this part of Scotland are, with respect to the distribution of pressure, in accordance with Buys Ballot's 'Law of the Winds,' the Ben Nevis winds do not fit in with such a distribution of pressure, but, on the contrary, point to a widely different distribution of pressure at the height of the observatory—4407 feet above the sea—as compared with the distribution at sea-level. In large storms, with a deep barometric depression in the centre, the Ben Nevis winds are practically the same as at lower levels; but with smaller storms, whose central depression is much less, great differences are presented. In such cases it is remarkable that with a cyclone covering Scotland, the North Sea, and Southern Norway, the winds frequently blow, not in accordance with the sea-level isobars, but in the opposite direction, suggesting an upper outflow from the cyclone towards the anti-cyclone adjoining it at the time. It is further remarkable that this outflowing seldom or never occurs when the centre of the storm is to the south or west, but only when it lies to the north or east, or in the region where at the time the weather is coldest and driest. If the wind on the hill-top is not at a right angle or a greater angle from the sea level wind, it is usually nearly the same as it. The supposed veering of the wind at great heights—required by the theory that a cyclone is a whirling column, drawing the air in spirally below and pouring it out spirally above—is so seldom observed as to be the exception, and not the rule. This important result, and the analogous observation that frequently in great storms of winds prostrate trees lie practically in one direction over wide regions, show impressively how much observation has yet to contribute before a satisfactory theory, or even a merely correct description of storms can be propounded.

"The winds at Säntis, Puy de Dôme, and other high-level European observatories, which may all be practically regarded as situated in anti-cyclonic regions, have been examined, and it is found that they show the closest agreement with the winds at low levels in the same regions. This result separates the Ben Nevis Observatory from other observatories, constituting it a class by itself, the differentiating cause being the circumstance that Ben Nevis alone lies in the central track of the European cyclones. This consideration emphasises the value of the Ben Nevis observations in all discussions of weather and atmospheric movements. It may be added that, with respect to the relatio of the winds to the low-level isobars, Ben Nevis Observatory more pronouncedly a high-level observatory in winter than i summer, or, more generally, in cold than in warm weather."

The influence of high winds upon barometric pressure has als been investigated. A comparison of readings of the baromet and anemometer at both the high and low level observatori shows that "in calm weather the two reduced barometers a practically the same, but with every increase of wind whic sweeps past the higher observatory the depression of th barometer inside steadily augments. It is not till a velocity more than 20 miles an hour is reached that the depressio amounts to one-hundredth of an inch. At 57 miles it is 0·0 inch, at 77 miles 0·104 inch, and at 99 miles 0·150 inch. forecasting weather it will be necessary to keep this effect high winds on the barometer constantly in mind, with the vie of arriving at a better approximation to the geographical di tribution of pressure at the time the forecasts are being framed

Relation of Differences of Temperature to those of Pressur

A discussion of the differences between simultaneous readin of pressure and temperature at the two observatories shows th "during the period of occurrence of an anti-cyclone, when th

FIG. 3.—Observatory covered with Fog Crystals—an Observer at Work.

temperature at the top of the mountain, with reference to th at Fort William, is highest, the pressure at the top, reduced sea-level, is 0·047 inch higher than at Fort William; and, the other hand, when the temperature at the top is very grea lower than the average as compared with that at Fort Willia the pressure at the top, reduced to sea-level, is 0·029 inch low than that at Fort William. There is, therefore, a mean diff ence of 0·076 inch of pressure for these two distinct types weather. The broad result is this, and it is clear and expli that when the higher observatory has the higher temperatu and also when the differences of temperature are small, then t reduced pressure at the top of the mountain is the greater of t two; but when the differences of temperature are large, th the reduced pressure at the top is the lesser of the two. . . . T result, which is altogether unexpected, raises questions of t greatest importance, affecting the theory of storms, the effect vertical movements of great masses of air on the baromet pressure which accompanies cyclones and anti-cyclones, and t necessity there is for some accurate knowledge of the absol amounts of aqueous vapour at different heights in the atn sphere under different weather conditions, and how this kno ledge may be arrived at from the readings of the dry and wet bulb thermometers under different atmospheric pressures. Ben Nevis, with its two observatories, one at the top, the other at the foot of the mountain, would, with a third half-way up the hill, afford unique facilities for the prosecution of this all-important hygrometric inquiry, which would, however, require considerable additions, for the time it is carried on, to the observatories' present appliances and staff."

St. Elmo's Fire and Thunderstorms.

"Cases of St. Elmo's Fire are not infrequent occurrences on Ben Nevis. The cases observed have mostly occurred during the night, and during the winter months from September to February. A careful discussion of these cases shows that the weather which precedes, accompanies, and follows has quite peculiar characteristics not only on Ben Nevis but also over the West of Europe generally; indeed, so well marked is the type of weather, and so notorious is it for its stormy character, that it is familiarly known at the observatory as 'St. Elmo's weather.' It is further observed that in almost every case another cyclone, with its spell of bad weather, follows the particular cyclone on the south-eastern side of which St. Elmo's Fire is observed.

"The winter thunderstorms are observed under the identical weather conditions under which St. Elmo's Fire occurs; that is, they invariably occur on the south-east side of the cyclone's centre, with the easterly passage of which they appear to be intimately connected. The thunderstorms and cases of sheet-lightning of Ben Nevis are essentially autumn and winter occurrences, 70 per cent. of the whole having occurred from September to February."

Electric Currents.

"Prof. C. Michie Smith has shown that on the edge of a dissolving mist the potential is lower than the normal, but higher on the edge of a condensing mist. Now, almost always when the top of Ben Nevis becomes clear for a short time, a strong current comes up the telegraph cable, while as soon as the summit is again enveloped the current is reversed. The connection between the moisture of the atmosphere and the earth currents is still further shown by the rainfall. During a fall of rain or snow the current nearly always passes down the cable; and in the case of a sudden shower the current has sometimes driven the mirror of the galvanometer violently off the scale. A cessation of the rain or snow generally has an exactly opposite effect. If it be assumed that the summit of Ben Nevis takes the potential of the masses of vapour covering it, and if we consider the earth-plate at the base as the earth, or zero of potential, it is obvious that the results confirm the theory advanced by Prof. Michie Smith, a conclusive proof of which would be of the greatest importance in investigations connected with thunderstorms."

Dust Particles in the Atmosphere.

Observations of the numbers of dust particles in the atmosphere have been made by means of the dust-counting apparatus devised by Mr. John Aitken in 1889. The results show a well-defined diurnal period, the number of particles being above the average in the afternoon, and below it in the morning.

"From the whole of the observations on Ben Nevis, the mean is 696 per cubic centimètre, the maximum being 14,400, while on several occasions the minimum fell to 0. In a large number of observations made by Mr. Aitken at Kingairloch, on the west shore of Loch Linnhe, the average number was 1600 particles per cubic centimetre; in London he found, on one occasion, 100,000, and this number was exceeded in Paris."

Many other investigations of a high scientific value have been made by the Ben Nevis observers, and the observations have furnished matter for discussion to a number of meteorologists. But though much has been done, it is evident from the reports issued by the directors of the observatory from time to time that still more important results can confidently be expected.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE seventh session of the Edinburgh summer meeting ended on Saturday. As regards number of students and scope of studies this meeting is still on the increase. Among the scientific courses may be noticed contemporary social evolution, by Prof. Patrick Geddes, comparative psychology by Prof. Lloyd Morgan, bionomics by Messrs. J. Arthur Thomson and Norman Wyld, history and principles of the sciences by Prof. Cargill Knott, Prof. Geddes, Mr. Bosanquet, and others, physiology of nutrition by Dr. Louis Irvine, a regional survey of Edinburgh and neighbourhood by Mr. J. G. Goodchild, Dr. Beard, Mr. Robert Turnbull, and Mr. S. H. Capper. A healthy sign is the attention given to practical work; thus the afternoon classes of botany, zoology, and geology were wholly practical. The less strictly scientific part of the month's miniature curriculum shows an almost equal development, indeed, so many excellent subjects were offered to the students that it must have been difficult to choose a course of study. Whatever the course selected, however, there is no doubt that the students derived considerable benefit from it.

THE following list of successful candidates for Royal exhibitions, national scholarships, and free studentships, has been issued by the Department of Science and Art:—National Scholarships for Mechanics—William Buchan (Glasgow), Frederick C. Lea (Crewe), James Eagles (Bury, Lancashire), Richard H. Cabena (Glasgow); National Scholarships for Chemistry and Physics—Albert Howard, (Much Wenlock, Salop), Francis R. Penn (Northampton), Andrew N. Meldrum (Aberdeen), William A. Bradley (Lee, Kent), Robert H. Jones (Manchester); National Scholarships for Biological subjects—Arthur O. Allen, (Walthamstow), Robert Sowter, (Brighouse, Yorks); National Scholarships—Charles F. Smith (Glasgow), John B. Chambers (London), John W. Hinchley (Lincoln), Henry J. Loveridge (Southsea, Portsmouth), Bernard C. Laws (Southsea, Portsmouth), Henry T. Davidge (London), Joseph B. Butters (Brighton), Henry H. Clements (Anahilt, Co. Down), Christopher Outhett (Burnley), William Macdonald (Manchester), William N. Platt (Chester); Royal Exhibitions—George S. Blake (Manchester), William H. Atherton, (Newcastle-on-Tyne), Ernest H. Bagnall (Manchester), Frank H. Newman (London), William A. Taylor (Crewe), Joseph H. Ivey (Camborne), Joe Crowther (Brighouse, Yorks); Free Studentships—John Schofield (Huddersfield), Joseph Jeffery (Birmingham), George A. Robertson (Oldham), Charles Kelly (Belfast), John Robinson (Belfast), Edmund F. W. Mondy (London).

SCIENTIFIC SERIALS.

American Journal of Science.—August.—We notice the following papers:—The use of cupric nitrate in the voltameter, and the electro-chemical equivalent of copper, by Frederick E. Beach. Copper nitrate solution of density 1·53 possesses certain advantages over the sulphate in voltameters. It is best to add one drop of saturated NH_4Cl solution. The dependence of the amount of copper deposited upon the current density does not appear until a density of 0·25 ampères per sq. cm. of electrode is reached, and then it is counteracted by adding more NH_4Cl. With the nitrate, the weight of copper deposited is practically independent of the temperature between 10° and 35°. The solution may be used a number of times. The equivalent of copper as determined from the nitrate voltameter agrees to four figures with that calculated from the best chemical determinations. But it is essential that the solution should be pure, and especially free from traces of nitrite.—On Mackintoshite, a new thorium and uranium mineral, by Wm. Earl Hidden; with analysis by W. F. Hillebrand. This is the original mineral of which thorogummite, discovered in 1891, is the alteration product. It is an opaque black mineral of hardness 5·5, and resembles zircon and thorite in form. It differs from thorogummite by the further oxidation of the uranium and the assumption of one molecule of water. It contains three molecules of silica, one of urania, three of thoria, and three of water.—On the reduction of nitric acid by ferrous salts, by Charlotte F. Roberts. The volume of nitric oxide disengaged, swept along by carbon dioxide and collected over caustic soda, was measured for the estimation of nitrates. The best results were obtained by passing the gas through KI solution before collecting, and estimating from the total volume of gas collected. Nitric oxide, being slightly soluble in caustic soda solution, must not be left long in contact with it. When the reaction takes place at high temperatures, some higher oxides of nitrogen may be formed, but this is corrected by the KI solution.—Concerning the structure of caoutchouc, by Hermann F. Lueders. Caoutchouc has no definite structure *per se*, and all apparent structure is only the result of the conditions under which its coagulation from the latex and subsequent solidification take place.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 21.—M. Lœwy in the chair.—On the equations of motion of a solid body moving in an indefinite liquid, by M. C. Maltézos.—On the alternations of colours presented by gratings, by M. Georges Meslin. If the achromatic fringes previously obtained by the author by means of a grating are observed more and more closely to the latter, they become more and more delicate, and certain colours begin to appear. The black fringes remain dark, but of two consecutive bright fringes the one appears violet and the other yellow; the same phenomena occurs along the whole field, which is covered with these two alternate colours. On moving the microscope slowly forward, a great variety of colours is observed, but the most usual are a mauve-violet associated with yellow, green combined with pink, or blue accompanied by white. The two colours in juxtaposition are thus nearly complementary, and during this displacement the same appearances recur several times, becoming more complex as the distance diminishes. The black fringes become very fine, the interval between two of them closes up, whilst the adjoining interval opens out and splits into coloured bands with a blue, pink, or yellow axis. In every case the phenomenon retains its periodic character. M. Meslin has succeeded in obtaining some very instructive photographs of these fringes.—On two new diseases of the mulberry, by MM. G. Boyer and F. Lambert. One of these diseases is caused by a bacterium, the other by a fungus. The disease caused by the *Bacterium mori*, chiefly affects young nursery mulberries, and arrests the development of their branches. It is manifested by dark brown patches at some points on the under side of the leaves and on the branches. Artificial patches in the parenchyma and in the veins of the leaves have been produced by inoculation. The bacterium when isolated and cultivated on artificial solid media, gives hemispherical colonies passing from white to yellow. The fungus disease is the more common of the two. The buds and leaves wither and dry up. The disease proceeds from the twigs to the branches and the trunk, and finally attacks the roots. The grey colour assumed by the wood is caused by the mycelium of a parasitic fungus not yet completely isolated. The mycelium is varicose, septiferous, and ramified. Its colour passes from white to a pale yellow, and finally to brown.—On the geogeny and stratigraphy of the coal basins of Central France, by M. A. Julien.—The Cambrian of the Herault, by MM. de Rouville, Delage, and Miguel. The authors have recognised three groups in the Herault Cambrian which they provisionally name Anteparadoxidian, Paradoxidian, and Postparadoxidian, corresponding to the Longmynd, Menevian, and Tremadoc groups respectively. In the third group, corresponding to the Tremadoc slates and Lingula flags, traces of Lingulæ have been found. An important fact concerning the stratigraphy of the country has been discovered in certain inversions extending over great lengths, unaccompanied by any indication of violent dislocation or rupture.

CONTENTS.

THURSDAY, SEPTEMBER 7, 1893.

THE PUBLIC HEALTH LABORATORY.

Public Health Laboratory Work. By Henry R. Kenwood, M.B., D.P.H., F.C.S., including Methods employed in Bacteriological Research, with Special Reference to the Examination of Air, Water, and Food, contributed by Robert Boyce, M.B. Crown 8vo. 491 pages. (London: H. K. Lewis, 1893.)

AN organised laboratory for the practical instruction of students of hygiene is a comparatively novel creation, the demand for which has principally arisen in connection with the various diplomas in Public Health (D.P.H.), which are now eagerly sought after by those of the younger generation of medical men who contemplate the possibility of becoming at some future time candidates for appointments as medical officers of health. Probably there are many persons who, whilst having a general acquaintance with the studies which are pursued in ordinary scientific institutions, are yet altogether ignorant of what is being done in these public health laboratories, which have grown up within recent years. A glance at the table of contents in the work before us will at once reveal what a wide and varied field this subject of public health is made to cover, including as it does the hygienic analysis of air and water, the examination of food (milk, butter, cheese, corn, bread, meat, alcoholic beverages, mustard, pepper, sugar, coffee, chocolate, tea, and tinned provisions), together with the "methods employed in bacteriological research, with special reference to the examination of air, water, and food." That this is a very comprehensive programme will be admitted by all, whilst it is equally patent to the initiated that it is one which it must be extremely difficult for a single teacher to conscientiously undertake, involving, as it does, an adequate knowledge of the most miscellaneous subjects. Inasmuch, however, as the ground covered is mainly of a chemical nature, it is obvious that the methods of work prescribed must be such as shall recommend themselves to chemists. In this connection it is interesting to note that the student is supposed to present himself at the public health laboratory without any previous knowledge of practical chemistry, at any rate as far as quantitative methods are concerned. Thus he has even to be initiated into the mysteries of such simple contrivances as the Bunsen burner, the pipe-clay triangle, and even the homely pestle and mortar, articles with which we should have supposed that most Board School children of the higher standards were now acquainted.

The first and largest section of the book is devoted to the subject of water analysis, the practice of which appears to form the *point de résistance* of the hygienic laboratory. For the information of those who have not had the benefit of receiving their instruction in such a laboratory we will cite a few examples of the practical methods which appear to be in vogue there. Chemists will be interested to learn that in using the balance the weights should be adjusted until "the index rests absolutely in a central and vertical position!" In determining the total solid matters in water, the only drying of the residue obtained by evaporation which is advocated is to place the dish containing it "for a few minutes in the water-oven," and even this appears to be regarded as an almost excessive refinement, for we are also informed that "when recourse is not had to the water-oven, the under-surface of the dish must be always carefully wiped dry before the dish and its contents are weighed." Such instructions might have been allowed to pass had some apology been made for the necessarily crude work alone to be expected from public health students, but when a little further on we are informed that the time involved in the evaporation of 100 c.c. of water is liable to introduce error through loss of organic matter in the water, and through the access of suspended matter from the air, it is obvious that the writer is under a wholly false impression as to the degree of accuracy obtainable by the methods he describes.

For the estimation of organic matter in water, the author has recourse principally to the so-called "albuminoid ammonia" process, but since the adaptation of the Kjeldahl method to water-analysis by Drown, there is now no reason why even in a poorly equipped laboratory an accurate determination of the total organic nitrogen should not be made, in addition to that of the variable fraction of this ingredient which makes its appearance on distilling the water with alkaline permanganate. The author describes the combustion process for organic carbon and nitrogen, but as something entirely beyond the sphere of the public health laboratory. The description given of this process would not appear to be derived from personal experience, whilst the suggestion that carbonic oxide is produced in the combustion, and volumetrically measured in the subsequent gas analysis, indicates but a very imperfect notion of what a satisfactory combustion with oxide of copper should accomplish.

We hardly think that the author has been successful in giving a lucid exposition of the important and much-vexed question of the activity of water on lead, for the statement that this activity "is favoured by either neutrality or slight alkalinity of the water (acidity, however, is even more important, since it aids the power of the water to carry the lead in solution)" is surely a somewhat circuitous way of saying that the lead-dissolving power of many waters is still wrapped in much obscurity.

Again, in the description of the preparation of normal solutions for volumetric analysis we read: "The number of grammes of the reagent are weighed out and dissolved in a litre of water," an inaccuracy which is repeated on the same page in the statement that a normal solution of hydrochloric acid is one consisting of "36·37 grms. of hydrochloric acid to a litre of distilled water."

In the chapter on coal-gas we are surprised to hear that the average gas supplied by the London companies contains 3 per cent. of carbonic acid: in all the published analyses of London coal-gas, and there are many, although the analysis only of Heidelberg gas (!) is recorded in the work before us, carbonic acid is either absent altogether or only present in small traces, for the gas managers are well aware that 3 per cent. of this ingredient, so prejudicial to the illuminating power, would entail great expense in bringing the luminosity of the gas up to the parliamentary standard.

Notwithstanding some shortcomings of this kind, the

 U

book is, on the whole, conveniently put together for the purpose it has in view, viz. the instruction of the public health student preparing for examination, for whose benefit, indeed, some of the chapters are actually furnished with schemes of analysis directing him how to make the best use of his time in the examination room.

But although this work may be well adapted to the requirements, such as they are, of the public health student, we cannot help thinking that the examples we have cited are alone sufficient to indicate the undesirability of what is in reality a very difficult branch of applied chemistry being taught outside the precincts of the chemical laboratory. In places where really accurate chemical work is not continually in progress, there must always be a tendency for rough and ready methods of analysis to creep in unchecked, with the inevitable result that a number of imperfectly trained persons are sent out into the world to undertake what ought to be regarded as highly responsible work. It is one of the most glaring anomalies of our *fin de siècle* civilisation indeed, that whilst but few educated persons would think of taking even the simplest medical remedy excepting under the advice of a duly qualified practitioner, such important questions as the water supply of a community, the detection of pernicious adulterations in articles of daily consumption, and the like, are frequently entrusted to persons who cannot furnish a shred of satisfactory evidence that they possess the necessary attainments for the performance of such responsible duties. It is deeply to be deplored, in the interests of the community, that the Institute of Chemistry has not hitherto succeeded in adequately illuminating the public on these matters. Thus, whilst the Institute has done much in prescribing educational curricula for the professional chemist, and in submitting a number of candidates to severe examinational tests, it has so far secured but little recognition for its Fellows from the general public, who certainly, as a rule, do not distinguish between them and the Fellows of the Chemical Society. In this connection, indeed, it cannot be sufficiently impressed on the laity that the Chemical Society is open, and in our opinion rightly, to *all comers who are, or profess to be, interested in chemical science*, and that its fellowship no more implies capacity to perform chemical work than fellowship of the Royal Geographical Society indicates any fitness to accompany Mr. Stanley across Central Africa, or Dr. Nansen to the Pole.

In conclusion we would point out that this type of book, embracing as it does a number of heterogeneous subjects prepared and boiled down into a sort of jelly for the pampered palate of the modern student, really raises a very important issue in connection with the much talked of technical education of the day. We perceive in the recent developments of such education a more and more marked tendency towards superficiality; year by year courses of instruction are made shorter and more composite by condensing primary subjects into a form supposed to be adapted to the requirements of particular bodies of men. All over the country we find teachers undertaking to provide a smattering in a number of different subjects, and a growing distaste on the part of students to devote time and attention to the deeper study of individual sciences. In such a subject as Public Health, the proverbial danger of a little knowledge is particularly menacing, and we are strongly of opinion that the student of this important subject, if he is to be properly trained, should receive the chemical, biological, and medical instruction involved, from a thorough chemist, a competent biologist, and a fully qualified medical man respectively, instead of imbibing only the views of a single teacher, who whilst professing a number of subjects is probably of but indifferent eminence in any one of them.

THE ARCTIC PROBLEM.

The Arctic Problem and Narrative of the Peary Relief Expedition of the Academy of Natural Sciences of Philadelphia. By Angelo Heilprin, leader of the Peary Relief Expedition. 8vo, pp. 165. (Philadelphia: Contemporary Publishing Co. 1893.)

PROF. HEILPRIN devotes almost half of his little book to the narrative of the voyage of the *Kite* to the relief of Peary, a narrative which he invests with lively interest, despite the fact that it has been anticipated by the writings of his subordinates. The record gives a very clear account of the voyage, and some admirable descriptions of Arctic scenery, supplemented by photographic reproductions printed in two tints, with a very realistic effect. Perhaps the most interesting chapter is that devoted to the naturalist of Peary's party, Mr. Verhoeff, who mysteriously disappeared just before the time fixed for returning home. A large number of men from the *Kite*, as well as Eskimos, prosecuted a minute search for several days, with the result that footprints and bits of paper were discovered on a glacier, movements on which were made difficult by the extremely rough condition of the ice. The natural inference is that Mr. Verhoeff, being alone, had fallen into a crevasse and perished there, and in this belief the search-party returned. A more romantic explanation is, however, given by some of his relatives, who believe that, enamoured of the wild life he had been leading, Mr. Verhoeff deliberately stayed behind with the object of making further explorations on his own account. Faint though the hope is, we could wish it to be true, and that when Lieutenant Peary approaches his farthest north in the new venture on which he is now embarked, he may find his old companion awaiting him.

The more important half of the book under consideration is Prof. Heilprin's clear and logical re-statement of what he aptly terms the Arctic problem. His language is frequently more perfervid than is usual amongst scientific writers on this side of the Atlantic, but his arguments are sound, and his conclusions cautious and reasonable. The discussion begins with a summary of three expeditions intended to start this summer on "the old trail" in quest of the highest latitude. On Nansen's project he wisely says little beyond stating the evidence for a transpolar current, and echoing the universal confidence in the gallant Norseman's pluck and perseverance. Nansen hopes, as our readers are aware, to approach the pole from the neighbourhood of the New Siberian Islands in longitude 140° E.

The Ekroll expedition, also a Norwegian project, has scarcely been heard about in Europe; in fact the only other reference to it which has come under our notice is a somewhat vague allusion in the annual address on geographical progress at the Paris Geographical Society. Ekroll intended, says Prof. Heilprin, to start in June, and travel northward from Cape Mohn in Spitzbergen (about longitude 20° E.), the feature of his expedition being the use of a composite structure capable of use as boat or sledge, according to the surface which has to be travelled over. This project is shown to be at least unsatisfactory, the risk of damage to the sledge (or boat) being too great, although the route to the north is an extremely suitable one. We do not know if Ekroll has set out. The third expedition is that of Peary, who is already *en route*, and intends to work northward over the frozen surface from the north coast of Greenland, where he did such brilliant service in 1892. Of the success of this enterprise Prof. Heilprin is confident; whether the Pole is reached or not he thinks that Peary has the best chance of breaking the record, and attaining a higher latitude than any of his predecessors.

Against the common plea that polar exploration having baffled the best endeavours of men whose heroism is beyond praise, any future effort is only waste of life, Prof. Heilprin urges the incontrovertible fact that in travel the almost impossible of yesterday is the easy accomplishment of to-morrow. He remarks that the ascent of Mont Blanc, at first a feat that made a man's reputation for life, is now a common tourist's pastime, while he might have added that Spitzbergen, formerly ranking as scarcely accessible Arctic land, is now within the reach of excursion steamers.

As to the best route to the Pole, he agrees that no expedition need waste its strength again on Smith's Sound, and he criticises with some severity the conclusions of the Royal Geographical Society twenty years ago before the despatch of the *Alert* and *Discovery*. The region north of Spitzbergen where Parry attained 82°45′ in 1827, only forty miles short of the point to which steam and the scientific advance of half a century enabled the best equipped expeditions to reach through Smith's Sound, certainly appears the most hopeful, and it is that in which any new expedition on a large scale that may be planned should undoubtedly make an attempt.

Without much novelty in argument or substance, Prof. Heilprin has set forth clearly and convincingly the plain issues involved in the Arctic problem, a problem which promises to be much before the public mind for some years to come.

OUR BOOK SHELF.

Vorlesung über Maxwell's Theorie der Electricität und des Lichtes. By Dr. Ludwig Boltzmann. Part I. pp. 139. (Leipzig: Johann A. Barth.)

THIS is a most interesting introduction to Maxwell's theories about electromagnetic actions. The whole question of generalised coordinates is introduced by means of models that enable the student to make a concrete picture to himself of a particular case of what he is studying. Some people may prefer to study subjects in the most general form, but the majority find very great difficulty in working out any advance on what they are taught by others without the assistance of some concrete case. In the case of most students it certainly helps them very much indeed to be provided with simple examples. Models may often do even more than facilitate the path of the student, they have before now pointed the way for the discoverer. As the mathematical part of Maxwell's theory is so largely an application of the principles of generalised coordinates this introduction to his theory is eminently interesting and suggestive. It is perhaps more suited to the state of scientific development on the Continent than in England. German and French electrical ideas had been so bound up with Coulomb and Ampère's laws of action at a distance that even the formulæ of Weber and Clausius which postulated propagation in time did not shake their faith in action at a distance, attracting and repelling electricities and currents and poles. Even yet Poincaré cannot get over the Coulomb law foundation of electrostatics. To such ideas a dynamical foundation such as Boltzmann has given should give a new direction. The whole process by which the electric current, the electrification, the magnetic pole, appear as generalised coordinates is brought out. The only objection that can be raised to the method from a British point of view is that the method is not drastic enough. It panders to the weaknesses of those who look upon the electric current as the important thing. It almost neglects the medium. It does not emphasise the connection of electric force and displacement, magnetic force and induction. It does not go even so far as Maxwell in formulating a theory as to the nature of the medium. It is too content with symbols. It introduces the propagation of the action through the medium almost as indirectly as Maxwell does. The forces and the displacements should be the foundations of electromagnetic theory and not the equation in generalised coordinates

$$2T = L_1\dot{y}_1^2 + 2M_{12}\dot{y}_1\dot{y}_2 + L_2\dot{y}_2^2$$

We must however be content to lead people gently. Prof. Boltzmann's introduction is certainly a move in the right direction, and there is every reason to think that the exertions of him and of Prof. Hertz are rapidly turning the current of continental study of electromagnetism into the right channel. In view of Prof. Boltzmann's recent interesting remarks on the value of dynamical models, it would be well worth while translating this work of his into English as an example for us how models can be employed successfully to illustrate a difficult subject. It is only of recent years that geometrical curve plotting has been popularised as a method of illustrating and facilitating mathematical investigations, and judiciously constructed models might perform a large part of a corresponding service for dynamics in the future.

Geology: an Elementary Hand-book. By A. J. Jukes-Browne. (London: Whittaker and Co., 1893.)

VIEWED as a rudimentary description of all branches of geology, Mr. Jukes-Browne's latest treatise is highly commendable. Its 248 pages contain something about everything geological. In a few places the information is rather disjointed, but that drawback is inseparable from an elementary work of limited dimensions which aims at giving students an idea as to the wide scope of geology. Of all the branches of the science, physical geology is given the most space, and rightly, for it is the division which is most intelligible to the general reader. The majority of the illustrations are rather coarse; nevertheless, they are usually of a helpful character. An objectional feature in the text is the frequent quotations from Geikie, Agassiz, and others. It seems to us that, in general, quotations should only be permissible in matters upon which a difference of opinion exists. But, on the whole, the book is a good one, and will be useful to students of elementary geology.

Recit de la Grande Expérience de l'Equilibre des Liqueurs. By Blaise Pascal. (Berlin: A. Asher and Co., 1893.)

This work forms No. 2 of the new series of publications of old books relating to meteorology and terrestrial magnetism, issued in facsimile by Prof. G. Hellmann, and was first printed in Paris in 1648. There is no copy of the work in the British Museum, and Dr. Hellmann has only been able to trace three copies, two of which are in Paris, and one in Breslau. This little work is of the greatest importance to the history of physics, to meteorology, and physical geography; it gives the first conclusive proof of the pressure of the atmosphere, and puts an end to the doctrine of the *horror vacui*. This famous experiment was made at Clermont Ferrand, and on the Puy de Dôme, on September 19, 1648, so that Pascal lost no time in making his discovery public, but it is not generally known that any account had been issued prior to the publication of the *Traitez de l'Equilibre*, printed in 1663. The work is prefaced by an interesting introduction by Prof. Hellmann, in which he refers to the doubt which exists whether the idea of the experiment was taken from Descartes. The latter has expressly asserted this to be the case, in two letters (dated June 11 and August 17, 1649), addressed to Carcavi, and the fact that Pascal never replied in any way to the letters in question, has induced many writers to adopt this view.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

The Organisation of Scientific Literature.

I have followed the correspondence in your columns on the question of the organisation of scientific literature with very keen interest, and should esteem it a favour to be allowed to add a few remarks to what has been said. There are two ways in which the present disorganisation might be dealt with. The first is exemplified in Prof. Bonney's "Year-book of Science"; that is to attempt to provide a key to the present complex state of affairs in the form of yearly abstracts. But even supposing this year-book (invaluable as it is) were comprehensive, which it admittedly is not, of what use would it be to the many workers who have neither the time nor the opportunity to spend hours in first-class libraries, nor the means to buy even a tolerable number of the innumerable magazines, journals, reports, &c., dealing with their special subject.

This infinite multiplicity of publication is the root of all the evil, and "Free Lance" strikes at it hard and well in his pamphlet on the organisation of science.

This brings us to the second method. As pointed out by "Free Lance," the only true solution of the difficulty is that in each country each subdivision of science should have its one central and accredited journal in which all papers on that subject worthy of publication should be published. In fact, a centralisation of publishing, with as much decentralisation of scientific meeting as the intellectual wants of the country may need.

Were this condition of things realised, then by consulting one or two journals in each country a specialist might easily, and comparatively cheaply, keep himself abreast of current work. In addition, an annual index or indexes of the books published in the various departments of science and in various countries, would render very great service.

Briefly, and in conclusion, my view of an ideal organisation of scientific literature is somewhat as follows:—

(1) In each country one central and accredited journal for each branch or subdivision of science.

(2) An international bureau working somewhat as follows:— (*a*) In each country the (α) papers (β) books and pamphlets, published in that country to be abstracted or indexed by well-paid men. (*b*) The several countries to exchange abstracts. (*c*) Finally, each country to translate the other abstracts and indexes into its own language, and publish these along with its own abstracts in, say, quarterly or monthly volumes, classified and subdivided for each science and branch of science.

In the case of such an international bureau proving impracticable, then each journal might abstract the work done in its department in other countries, after the admirable manner of the Chemical Society.

It is to be hoped that the British Association this year will take up the question seriously and in its widest aspect. There is no use organising one portion of science and leaving the remainder in disorder. F. G. Donnan.

Ardmore Terrace, Holywood, Co. Down, August 28.

Several of your correspondents have called attention to the importance of distributing copies of papers in quarters where they are likely to be read. It may therefore be well to emphasise the fact that the *Philosophical Magazine* refuses to supply *gratuitous* copies. When this fact is appreciated, I think most persons will see that it is rather an unbusinesslike proceeding to pay the *Philosophical Magazine* for separate copies, when they can be obtained for nothing by communicating the paper to a society.

The "full publication of . . . papers of the societies, &c.," as recommended by Mr. Trotter, would be an infringement of copyright, and would lead to the Physical Society becoming more closely acquainted with the mysteries of the Chancery Division than its members would probably desire.

The Physical Society is a young and precocious one, and, in conjunction with its partner, the *Philosophical Magazine*, would doubtless like to obtain a monopoly of all mathematical papers except those strictly denominated *pure*, which it does not care about. But its legitimate sphere of action is *experimental and applied science*, and if it shows a disposition to poach upon the preserves of its neighbours it cannot fail to excite hostility.

I do not see any objection to the word "physicist," the literal meaning of which is "naturalist"; but is not the word "scientific" more appropriate to this discussion than "physical"? A. B. Basset.

Hotel de Russie, Ems, Germany, September 3.

Drought and Heat at Shirenewton Hall in 1893.

Rain.

Month.	1893.	Average.	Excess or defect in 1893.	Most rain in a day.	Number of rainy days in 1893.	Number of days with at least a quarter of an inch.
	Inches.	Inches.	Inches.	Inches		
March	0·4	2·7	−2·3	0·170	5	0
April	0·2	2·1	−1·9	0·091	4	0
May	2·6	3·1	−0·5	0·880	9	3
June	1·8	2·6	−0·8	1·010	10	1
July	2·9	3·7	−0·8	0·660	12	4
August (to 17th)	1·8	2·1	−0·3	0·660	8	2
Total	9·7	16·3	−6·3	1·010	48	10

Since March 1, 122 days without rain.

Heat in Shade, 1893.

Month.	Number of days the heat was above		
	60°	70°	80°
April	25	9	2
May	28	15	1
June	30	21	6
July	31	21	5
August (to 17th) ...	17	17	8

Temperature, 80° and above.

Month.	°	Month.	°
April 20	82·8	July 3	83·5
,, 21	82·2	,, 6	83·5
May 12	80·0	,, 7	90·7
June 13	80·4	Aug. 9	86·7
,, 15	82·8	,, 10	83·0
,, 16	82·0	,, 12	80·0
,, 17	84·3	,, 13	86·0
,, 18	83·8	,, 14	86·5
,, 19	88·9	,, 15	88·5
July 1	86·0	,, 16	83·6
,, 2	88·0	,, 17	86·0

Most of the rain fell in thunderstorms, but their area was very limited; the amount in that of June 15 within 5 miles of this place is an example:—

Caldicot Hall ...	0·04	Itton Court	1·50
Dennel Hill	0·17	Piercefield Park	1·79
Wirewoods Green	0·56	The Mount, Chepstow	1·96
Shirenewton Hall	1·01		

		in.		in.
The rainfall in	May	was 2·6	; of this	2·4 fell from 15th to 20th.
,,	June	,, 1·8	,,	1·0 fell on 15th.
,,	July	,, 2·9	,,	1·1 fell from 10th to 15th, and 1·0 on 18th and 19th.
,,	Aug. (to 17th)	,, 1·8	,,	1·0 fell on 1st to 3rd, and 0·6 on 10th.

Thus, of the total rainfall (9·7), 7·1 inches fell on 17 days out of the 170 days. On August 9 there was no rain, but more lightning than I had seen since the memorable storm of August 9, 1843. It commenced at 9 p.m. and lasted five hours. From very frequent counting there could not be less than 10,000 flashes (the estimate was 11,540). For three hours the most number of flashes in a minute was 121, and the least 39. Before the storm of June 15 the ground was dry to the depth of 15 inches, and this 1 inch of rain only penetrated 2 inches. The long intervals of drought have parched the ground, so that we are still suffering from want of rain.

The Drought and Heat of 1893.

The results of an unusual occurrence like the present season show as clearly as instrumental observations the exceptional character. We have a very near copy of the drought of 1868–

1870; *i.e.* Monmouthshire is repeating what in 1868–70 occurred in Nottinghamshire. Flowers and fruit have been a month earlier than usual, their period has been of short duration, and insect pests have been very great. There has been an extraordinary abundance of apples, pears, plums, cherries, gooseberries, currants, field mushrooms, butterflies, moths, flies, caterpillars, cuckoo-spit aphis, slugs, and wasps. The tree-wasp, which is rare, has had many nests, and, as the structure is not generally known, my son has taken the enclosed photograph, which clearly shows it. The tree-wasp's nest is built much earlier than that of the ordinary wasp, and equally large, a low bush being the situation usually selected. Nightingales and cuckoos have been very numerous. Grass is now being mown for hay, and four to five acres will only yield a ton, whilst the straw of corn is shorter than ever before known. Trees are also very bare of leaves. Water is scarce, as many springs have been dry for some weeks. In June the trees and shrubs were as if varnished from extensive honeydew, which the thunderstorm cleared away. Strawberries are blooming a second time, and there are many plants seeding that do not usually seed here.

E. J. LOWE.

Some Recent Restorations of Dinosaurs.

UNDER the above title, an illustrated article, by Mr. R. Lydekker, appears in NATURE, July 27, 1893, p. 302. This purports to give a summary of what has recently been done in restoring certain remarkable forms of extinct reptiles. Most of the statements made are correct, but with them are a number of serious errors that may mislead readers not familiar with the subject. As the restorations given are, with one exception, my own, and represent indirectly several years' work in the field and museum, I trust you will allow me to call attention to some mistakes in this article, which were perhaps made by Mr. Lydekker through inadvertence, or from his not having seen the specimens described.

In the introduction, the date 1878 is given for the first of my memoirs on Jurassic Dinosaurs; whereas in the previous year I described (1) the earliest of the huge Sauropoda found in America, proposing the family name Atlantosauridæ for the genera Atlantosaurus and Apatosaurus; (2) various carnivorous Dinosaurs of the present order Theropoda, including the genera Allosaurus and Dryptosaurus; (3) the Stegosauria, represented by Stegosaurus, the first American genus of the group; and (4) several small forms of true Ornithopoda, including Nanosaurus. The family Atlantosauridæ, the sub-order Stegosauria, and the genera here mentioned, were thus established by me in 1877 in the *American Journal of Science*, vol. xiv.; a small matter in itself, but the beginning of a long investigation.

The first restoration given by Mr. Lydekker, Fig. 1, is that of my *Brontosaurus excelsus*, reduced from an outline sketch published, as stated, in August, 1883; but no reason is assigned for not using, especially in a summary of recent work, my more complete restoration of 1891, which includes the results of much additional study. This figure represents a typical member of the order I have called Sauropoda, but in the text the name used is Sauropsida, a much more comprehensive term.

The second restoration, Fig. 2, called "A Carnivorous Dinosaur," is said to have been reproduced from my figures. This must be a mistake. It is evidently printed from one of my *clichés*, and is certainly used without authority. Moreover, the name I gave to the animal represented (*Ceratosaurus nasicornis*) is not even mentioned, but it is incidentally stated that my genus Ceratosaurus, based on this unique specimen, is inseparable from the European Megalosaurus. This statement could not be fairly made by anyone familiar with the type specimens of the two genera, or even with the literature. Only a few authentic remains of Megalosaurus are known, and I have studied all the important specimens with care. There is no evidence that the skulls are identical in the two forms, and much against it. The plano-concave cervical vertebræ of Ceratosaurus, unknown in any other Dinosaur, are radically different from the convexo-concave vertebræ of Megalosaurus. The complete co-ossification of all the pelvic elements of Ceratosaurus is another distinctive character, and the union of the metatarsals also is important. An elementary knowledge of the structure of Dinosaurs is quite sufficient to show any anatomist that the two belong to genera widely different, and to indicate for them distinct families. Additional remains, obtained since Ceratosaurus was described, have in great part removed the objection that the co-ossification mentioned may have been pathological. My restoration will be found in the American *Journal of Science* for October, 1892, and in the *Geological Magazine* for April, 1893.

The third figure given by Mr. Lydekker is a reduced copy of my restoration of *Stegosaurus ungulatus*, published in August, 1891. This reptile he calls Hypsirophus, giving that name priority over Stegosaurus, but without citing any authority for such a statement. A single reference to the literature would have proved this to be a mistake, as Stegosaurus was published by me in 1877, as above stated (*American Journal of Science* (3), vol. xiv. p. 513), while the name Hypsirophus was given by Cope in 1878 (*American Naturalist*, vol. xii. p. 188). Another error of less importance is in regard to the specimen on which the restoration is based, although this was clearly stated in the description accompanying my figure. The type specimen of *Stegosaurus ungulatus* Mr. Lydekker apparently confuses with a second skeleton, of a different species, which was even more perfect when found.

The fourth restoration given is a reduced copy of my figure of the skeleton of *Triceratops prorsus*, which, like the preceding restorations, has already been published by me, both in the *American Journal of Science* and in the *Geological Magazine*. Here again Mr. Lydekker rejects my generic name Triceratops, and even puts that and another genus of mine (Ceratops) as synonyms of Agathaumas without giving any reasons for doing so. The type specimens of the literature would show any candid anatomist that the three forms named, and another which I called Torosaurus, are all distinct genera, separated by well-defined characters. These characters I have given in detail in the *American Journal of Science*, accompanied by accurate figures of the forms I have described (vol. xliii. pp. 81–84, plates ii. and iii., January, 1892).

The remaining restoration given in Fig. 5 represents a well-known skeleton of Iguanodon in the Royal Museum of Belgium. In regard to this figure I have at present nothing to say, except that I have carefully studied the original specimen and those found with it, having made several visits to Brussels for this purpose.

The omissions from this article are perhaps as noteworthy as what it contains. No reference is made to two restorations of American Dinosaurs which I have recently published; Claosaurus from the Cretaceous, and Anchisaurus from the Triassic, although each is based on a nearly perfect skeleton. Both of these restorations have appeared in the *American Journal of Science* and also in the *Geological Magazine* within the past year. Mr. Lydekker likewise omits the restoration of Megalosaurus, which he has lately given to the public, although many palæontologists would be glad to know more about it, especially about the remains on which it is based.

Mr. Lydekker begins his article by referring to the discouragements of palæontologists in the investigation of fossil vertebrates, but ends with some words of encouragement. He might have added that one discouragement to active workers who devote years to exploration and study is to have the results of their labour used without due credit, or disparaged by those who do not understand them. O. C. MARSH.

Yale University, New Haven, Conn., August 15.

Insects Attracted by Solanum.

SIR JOHN LUBBOCK, in his "British Wild Flowers in Relation to Insects," remarks (p. 133) that *Solanum* is little visited by insects. Darwin, in "Effects of Cross and Self Fertilisation," has some observations (p. 387) to the same effect. It will therefore be useful to record that, however it may be with European species, an abundant *Solanum* of New Mexico is very attractive to insects. The species in question is *S. elæagnifolium*, Cav., which has deep lilac flowers not unlike those of the potato. I was especially successful in capturing interesting aculeate hymenoptera on this plant, as the following list will show. All listed were taken in Las Cruces, and all (except the *Megacilissa*, July 12) on July 13.

Hymenoptera taken on Solanum elæagnifolium, 1893.

Ammophila pruinosa, Cr. ♀.
,, *varipes*, Cr.
Anthophora urbana, Cr. ♀.
Halictus, sp. ♀.
Megacilissa gloriosa, Fox.
Melissodes menuacha, Cr. var.? ♀
Myzine frontalis, Cr. MS.
Mysson texanus, Cr. ♀.
,, n. sp.
Odynerus bravo, Sauss. (new to U.S. fauna).
Pelopæus servillei, Lef.
Plenoculus, n. sp.
Sphærophthalma coccineohirta, Blake, ♂ var.
Stizus agilis, Sm.
,, *flavus*, Cam. (new to U.S. fauna).
Tachysphex, sp. ♀.
Tachytes elongatus, Cr. ♂.
Trypoxylon texense, Sauss.

For the identifications of the species I am indebted to Mr. W. J. Fox. T. D. A. COCKERELL.

Agricultural College, Las Cruces, New Mexico, U.S.A. August 16.

Old and New Astronomy.

IN your notice of the "Old and New Astronomy," your reviewer has, I think, misunderstood the passage with respect to reflecting telescopes, on p. 45, which he refers to as indicating that Mr. Proctor supposed that the image in the principal focus of a reflecting telescope was affected with chromatic aberration or false colouring. Section 97, to which I conclude your reviewer refers, evidently refers to the magnified image which enters the eye of an observer when a "*real image* of an object is submitted to microscopical examination."

No one who knew Mr. Proctor could suppose him to make such a mistake; and that he was perfectly well aware that the image thrown by a reflector was not affected with chromatic aberration, would, I think, have been evident to your reviewer if he had read to the bottom of the page, where in Section 101 Mr. Proctor says:—"Newton supposed that it was impossible to get rid of this defect (*i.e.* chromatic aberration), and therefore turned his attention to the construction of reflectors," a clear proof that Mr. Proctor was in no doubt upon the subject, and only referred in the previous passage to the false colouring of an image formed by a lens. S. D. PROCTOR-SMYTH.

8 Duncairn Street, Belfast, August 23.

MRS. PROCTOR-SMYTH is in error in supposing that my note referred to Section 97 of "Old and New Astronomy." I referred to Section 100, in which the author says "the pencil of light proceeding from a point such as P, Figs. 14, 16, and 18, consists of rays of different refrangibility, and therefore *not converging to a focal point such as p but to a focal line in the axis of the pencil.*" (The italics are mine.) Fig. 18 is a diagram of the formation of a real image by a reflector. The reference to Fig. 18 may have been a slip; if so, it should have been corrected in the completed volume, as otherwise the student, reading the subsequent paragraphs, to which Mrs. Proctor-Smyth refers, is confused as to what the author really means, and is doubtful whether the reflector does or does not suffer from chromatic aberration. THE REVIEWER.

Suicide of Rattlesnake.

ANOTHER question raised by the late snake story is, How long does it take to drown snakes? Some of the non-poisonous kind at the Zoological Gardens, in certain states of the weather, are fond of hanging themselves over the edge of their tank, with their heads immersed in the water, for as long as an hour together. E. L. GARBETT.

August 29.

THE EARLY ASTERISMS.

I.

NOT very many years ago, when the literature of China and India was as a sealed book, and the hieroglyphics of Egypt and the wedges of Babylonia were still unread, we had to depend for the earliest traces of astronomical observation upon the literatures of Greece and Syria, and according to these sources the asterisms first specialised and named were as follows:—

The Great Bear	Job (xxxviii. 31), Homer.
Orion	Job (ix. 9), Homer, Hesiod.
Pleiades, Heiades	Job (xxxviii. 31), Homer, Hesiod.
Sirius, the Great Dog ...	Hesiod (viii.), the name; Homer called it the Star of Autumn.
Aldebaran, the Bull... ...	Homer, Hesiod.
Arcturus	Job, Homer, Hesiod.
The Little Bear	Thales, Eudoxus, Aratus,
The Dragon	Eudoxus, Aratus.

It follows from the investigation into the orientation of Egyptian temples that the stars α Ursæ Majoris, Capella, Antares, Phact, and α Centauri were carefully observed, some of them as early as 5000 B.C., the others between 4000 and 3000 B.C. Further, that the constellations of the Thigh (Ursa Major), the Hippopotamus (Draco), the Bull, and the Scorpion had been established in Pyramid times.

It becomes important therefore, if we recognise this as the dawn of astronomy in Egypt, to see if any information is extant, giving us information concerning Babylonia, so that we may be able to compare the observations made in the two regions, not only with a view of tracing the relative times at which they were made, but to gather from these any conclusions that may be suggested in the course of the inquiry.

The inquiry must be limited to certain detailed points; we know quite well already, as I stated in the introduction, that the omen tablets of Sargon I., who reigned in Babylon 3700 B.C., prove unquestionably that astronomy had been cultivated for thousands of years before that date.[1] But to institute a comparison we must leave the general and come to the particular. I will begin with the northern constellations, as it follows from my researches that very early at Denderah and Thebes, and in all probability at On, temples were erected for their worship—the worship of Anubis or Set, as I have shown, that is α Ursæ Majoris and γ Draconis.

According to Maspero, Set formed one of the divine dynasties at On, and the northern stars seem to have been worshipped there. I suppose there is now no question among Egyptologists that the gods Set, Sit, Typhon, Bes, Sutekh, are identical. It is also equally well known that Sutekh was a god of the Canaanites[2] that the hippopotamus, the emblem of Set and Typhon, was the hieroglyph of the Babylonian god Baal,[3] and Bes is identified with Set in the book of the dead.[4]

It is also stated by Maspero that at Memphis[5] [time not given] there were temples dedicated to Soutekh and Baal. In the article on the circumpolar stars I have suggested that they were taken as typifying the powers of darkness and of the lower world, and I believe it is conceded by Egyptologists that Anubis in jackal form preceded Osiris in this capacity.

In the exact centre of the circular zodiac of Denderah we find the jackal located at the pole of the equator; it obviously represents the present Little Bear.

Do we get the jackal constellation in Babylon astronomy? Of this there is no question, and in early times. Jensen refers[1] to the various readings "jackal" and "leopard," and states that it is only doubtful whether by this figure the *god* ANU or the *pole of the ecliptic* ANU is meant. Either will certainly serve our present purpose.

I know not whether the similarity in the words Anu and Anubis results merely from a coincidence, but it is quite certain that the seven stars in Ursa Minor make a very good jackal with pendant tail, as generally represented by the Egyptians, and that they form the nearest compact constellation to the pole of the ecliptic.

It seems extremely probable, therefore, that the worship of the circumpolar stars went on in Babylonia as well as in Egypt in the earliest times we can get at.

A very wonderful thing also is that, apparently in very early times, the Babylonians had made out the pole of the equator as contradistinguished from the pole of the ecliptic. This they called Bīl. With this Jensen finds no star associated,[2] but 6000 B.C. this pole would be not far removed from those stars in the present constellation Draco, out of which I have suggested the old Egyptian asterism of the hippopotamus was formed.

Now I gather from Prof. Sayce[3] that Anu and Bīl ranked as two members of a triad from the commencement of the Semitic period, the third member being probably a southern star symbolised as we shall see in the sequel.

The whole triad was stellar and two-thirds circumpolar; it was only in later ages that we get a triad consisting of sun, moon, and Venus,[4] Venus being replaced at Babylon by Sirius.[5]

To these two northern divinities temples were built, both were worshipped in one temple at Babylon,[6] which must therefore have been oriented due north, and the pole of the equator, the altitude of which (equal to the latitude of the place) was probably in some way indicated. Here there was no rising and setting observations, for Eridu the most southern of the old Babylonian cities had about the same latitude as Bubastis, in Egypt. The pole of the ecliptic (Anu) would revolve round the pole of the equator (Bīl) always above the horizon.

So that since	Sutech = Anu
and	Baal = Bīl,

the temple at Memphis to those divinities reported by Maspero (see *ante*) must have been oriented in the same way as the one at Babylon; and if the above evidence be considered strong enough to enable us to associate the Babylonian Bīl with the Egyptian Taurt, we have not only Ursa Minor but Draco represented in the mythology both of Egypt and early Babylonia.

I gather from Prof. Sayce's "Hibbert Lectures"[7] that there is a distinct evidence of a change of thought with regard to Anu. Observations of stars near the pole of the ecliptic appear to have been utilised before they were taken as representing either the superior or inferior powers—before in fact the Anubis or Set stage *quâ* Egypt was reached. After this had been accomplished there was still another advance in which Anu assigns places to sun, moon, and evening star, and symbolises the forces of nature.

It seems probable that the same rectangular arrangement of temples which held in Egypt, held also in Babylonia,[8] and this perhaps may be the reason why Bīl seems so often to refer to the sun, whereas it was the name given to the combined worship. Sometimes, on the other hand, the worship of the stars is distinctly

[1] Besides the book on omens we have "The Observations of Bel," or "Illumination of Bel" (Mul-lil), seventy-two books dealing with conjunctions of Sun and Moon, phases of Venus, and appearance of comets. "Hibbert Lectures," (Sayce, 1887, 29).

[2] P. 147.
[3] Sayce, p. 193.
[4] Sayce, p. 193.
[5] Jensen, p. 149.
[6] Sayce, p. 439.
[7] P. 190.
[8] In the ceremonials in the temples also the statues of the gods in boats or arks were carried in procession. Sayce, p. 280.

referred to as taking place in a solar temple. Thus at Marduk's temple, E-Sagila we are told "two hours after nightfall the priest must come and take of the waters of the river, must enter into the presence of Bīl, and putting on a stole in the presence of Bīl must say this prayer," &c.[1] The temple then will have been probably oriented to the north.

Nor was this all; movements in relation to the ecliptic had been differentiated from movements in relation to the equator. We have inscriptions running:—

"*The way in reference to Anu,*" that is the ecliptic with its pole at Anu.

"*The way in reference to Bīl,*" the equator with its pole at Bīl.

In other words, the daily and yearly apparent movements of the heavenly bodies were clearly distinguished, while we note also

Kabal šami, "the middle of the Heavens" defining the meridian.

So far as I have been able to gather any myth like that of Horus involving combats between the sun and circumpolar star gods is entirely lacking, but a similar myth in relation to some of the ecliptic constellations is among the best known.

The Ecliptic Constellations.

I have already in previous articles pointed out that at On we seemed limited to Set as a stellar divinity; so soon as pyramid times are reached, however, this is changed.

I have given before the list of the gods of Heliopolis, and have shown that with the exception of Sit none are stellar. But we find in pyramid times the list is increased; only the sun gods Ra, Horus, Osiris, are common to the two. As new divinities we have[2]:—

Isis.
Hathor.
Nephthys.
Ptah.
Selkit.
Sokhit.

Of these the first two and the last two undoubtedly symbolised stars, and there can be no question that the temples of Isis built at the pyramids, Bubastis, Tanis, and elsewhere, were built to watch the rising of some of them.

The temple of Saïs, as I have said, had east and west walls, and so had Memphis, according to Lepsius. The form of Isis at Saïs was the goddess Neith, which, according to some authorities, was the precursor of Athene. The temple of Athene at Athens was oriented to the Pleiades.

There is also no question that the goddess Selk symbolised Antares.

We find ourselves then in the presence of the worship of the sun and stars in the constellations of the ecliptic in Egypt, in pyramid times, and in constellations connected with the Equinoxes; for if we are right above the Pleiades and Antares these are the stars which would herald the sunrise at the Vernal and Autumnal Equinox respectively, when the sun was in Taurus and Scorpion.

Now associated with the introduction of these new worships in pyramid times was the worship of the bull Apis.

The worship of Apis preceded the building of pyramids. Mini is credited by some authors with its introduction,[3] but at any rate Kakau of the second dynasty issued proclamations regarding it,[4] and a statue of Hapi was in the temple of Cheops.[5]

The first question which now arises is When were these constellations established in Babylonia? Is there any information?

[3] Maspero, *op. cit.* p. 44. note.
[4] Maspero, *op. cit.* p. 64.
[5] Maspero, *op. cit.* p. 46.

With regard to the constellations of the Bull and Scorpion, there does seem to be some information, and on this point in a subsequent article I shall have to refer at some length to Jensen's recent important book.[1]

J. NORMAN LOCKYER.

(*To be continued.*)

PUBLICATIONS OF THE ZOOLOGICAL STATION AT NAPLES.[2]

DURING the winter of 1876, when the Zoological Station was already a fact in brick and mortar, and my late friend, Mr. Frank Balfour, had already shown by his famous work on the Elasmobranch Development how profitable its arrangements might turn out for the progress of research in morphology, I began to busy myself with the literary phase of my enterprise. From the very beginning it had been my intention to erect not merely a simple laboratory, in which a more or less long series of "Contributions to the knowledge" of all sorts of groups or problems ought to be worked out, but to create an organisation which by its own power and weight might influence the further progress and development of morphological science in the direction of greater concentration and by production of such scientific work as could hardly be taken up and still less carried through by individual effort alone. Of course the Zoological Station ought to have its own Journal, similar to the many Journals or Zeitschriften or Archives of other and perhaps less powerful institutions or societies, but I hoped to do more than that. If my ideas of, and confidence in, the future development of the Zoological Station were right, more important productions might be expected from it, and thus it became only a question of organisation and combination of means and ends to secure such a result. I had learned by almost daily experience how difficult, almost hopeless, it was to succeed with the specific determination of all the numberless organisms, worms, crustaceans, hydroids, tunicates, &c., &c., which our fishermen brought to light day by day. Even if the library of the Zoological Station at that time had been complete enough, it would have been almost impossible to ascertain the names of all these creatures, the descriptions and figures in former works being far too incomplete and too superficial to enable even specialists of all these groups to decide which name belonged to which animal. All attempts to form a well-determined collection of any group—not excluding even the larger crustaceans, echinoderms, and medusæ—failed, and sometimes to such a degree that my assistants and myself simply felt ourselves in the midst of chaos. This may sound strange to conchologists, ornithologists, and entomologists, who can rely on splendid monographs and innumerable synopsis and similar works for classification, but it is nevertheless a deplorable fact for the marine fauna of almost all the seas. And the want is greatly felt, for the marine organisms in by far the greater number of cases require not only an outside investigation by a simple magnifying glass, but microscopical examination of anatomy and development, both embryological and larval, to state definitely to which species they belong, the sexual difference being often so great as to have given occasion to create different genera and even groups for male and female of the same species, and the larval forms in many cases being so utterly unlike the adults that they have been classified in different orders! Tornaria is now known as the larva of Balanoglossus, whereas not long ago it was

[1] "Kosmologie der Babylonier," p. 315, *et seq.*
[2] "Systematik und Faunistik der Pelagischen Copepoda des Golfes von Neapel," von Wilh. Giesbrecht. XIX. "Monograph of the Fauna and Flora of the Gulf of Naples," published by the Naples Zoological Station, 1892, pp. 1–831, pl. 1–54.

supposed to belong to the Echinoderms. What can be more unlike each other than male and female of *Bonellia viridis?* How long did it take to ascertain the true relation of the so-called Hectocotylus to the Cephalopods? And only a few years ago a simple appendage of a well-known mollusc, Tethys, was described as a special genus by one of the most distinguished French zoologists. Such being the difficulties it can hardly be wondered at that, for instance, the same species of a Pycnogonid has had the honour of being described under nine specific and generic names, the greater part of them even by the same author, because he ignored that male and female differed, and that their larval stages again differed from each other and from the adult.

It was then that I planned the publication of a great series of monographs under the title "Fauna and Flora of the Gulf of Naples." Several of my assistants and myself set to work, each one selecting a group of lower marine animals. The main object of these monographs was to create a firm basis for systematical knowledge, but in the meantime I left everybody free to incorporate as much of anatomy, histology, and embryology as he thought convenient, thus giving greater variety to the monographs, and leaving the authors free to follow up those lines of research for which they had the greatest interest.

I wished to lay great stress upon illustrations. In looking over the existing iconography of the lower marine animals, and comparing them with those of terrestrial animals, the inferiority of existing illustrations of the former was apparent, and especially as regards the reproduction of the colouring of the living marine organisms. Colour in animals may have relatively little scientific interest compared with structure, nevertheless it has a meaning, and its good reproduction facilitates greatly the recognition of the species. Besides, practical reasons spoke very much in favour of good coloured illustrations as a means to facilitate the sale of the monographs, which were to be published on subscription, and as the safest way for covering the great expenses which were to be incurred.

I remember in this regard a conversation which I had with the great German publisher, Wilh. Engelmann, of Leipzig, to whom I offered the commission of all the publications of the Zoological Station. When discussing the project of the "Fauna and Flora" I asked his advice as to the number of copies to be printed, and proposed myself 500. Engelmann almost fainted when I pronounced that number. "My dear friend," exclaimed he, "you are going to ruin yourself! There is not the remotest possibility of such a number! Of such costly publications as you project hardly one hundred copies are sold, and if we print 150 copies, it will be more than enough." I remonstrated, and insisted on at least 300, and as I intended to pay all the expenses, Dr. Engelmann on his side kindly reducing the cost of commission to five per cent., I felt pretty safe, to find the necessary number of subscribers in the course of time—a confidence which was not in the least shared by Dr. Engelmann, who called me a Phantast, and a Utopian—denominations to which I had already become so much used that they made hardly any impression upon me. And I have only to regret that I did not insist on my first proposition, for the first volume of the "Fauna and Flora," the monograph on the Ctenophora by Prof. Chun, has been out of print for almost ten years, and single copies are sold at double the original price.

The secret of this success consisted largely in the magnificent plates which accompanied this and the following volumes. It is true that the high scientific standard of these monographs and the low rate of subscription for them caused their sale among all the more important libraries and universities, but the large number of public and private libraries who subscribed to the "Fauna and Flora" did so partly out of sympathy for the Zoological Station, and partly out of enthusiasm for the splendid illustrations which accompany the greater part of the nineteen published volumes, and are executed in the most masterly way by the celebrated lithographic firm of Werner and Winter, at Frankfurt-on-Maine. In fact, it is not too much to say that the world-wide fame of this firm has partly been created by the first volume of the "Fauna and Flora of the Gulf of Naples," whose illustrations were all personally engraved by Mr. Winter himself.

It is doubtless true that the cost of production of these plates is very great; nevertheless, I may be permitted to state that the balance-sheet of the "Fauna and Flora" shows how justly I appreciated the chances when I began this large publication; and though since the last four or five years the number of subscribers has decreased, chiefly by death, the Zoological Station hopes, nevertheless, to continue the series of monographs in the same way for many years to come.

The volume which I have under review is a very fair specimen of the value of these plates, for I hardly say too much if I state my conviction that nowhere have illustrations of Copepoda been produced to rival those of Dr. Giesbrecht's volume. One can hardly look on the first five plates without wishing that some of these fantastical and splendid figures might find their way even beyond the range of scientific literature, and serve as decorative elements in art and industry, where birds, butterflies, and flowers already occupy such an enormous field.

Thirty years have elapsed since the appearance of Claus's well-known monograph of the free-living Copepoda. Many smaller, and even some larger works have been published in the interval, enlarging the field to such a degree that it seemed advisable to divide the whole group into several parts for a new monographical study. Dr. Giesbrecht selected the *pelagic* marine forms instead of the *littoral* ones, partly on account of their better qualification for anatomical and ontogenetical researches, partly because they are yet less known than the others, and lastly, because he thinks they include the more ancestral forms of the whole entomostracous crustaceans. The bulky volume lying before us forms only the first part of the monograph, treating the systematical and faunistical chapters. But as such it gives much more than its title announces, for not only have the pelagic Copepoda of the Gulf of Naples been examined, but the whole mass of forms resulting from the oceanic cruise of the *Vettor Pisani*, an Italian corvette, and captured and carefully preserved by Capt. Chierchia, so well known among biologists, are included in Giesbrecht's work. Altogether, this volume treats of 298 species of pelagic Copepoda; 125 belong to the fauna of the Gulf of Naples, whilst 229 have been captured by Capt. Chierchia all over the globe. If one compares the last number with that of the *Challenger* expedition, where only 85 species of Copepoda are reported, one can imagine with what industry Capt. Chierchia went to work, and how carefully Dr. Giesbrecht examined the material.

The descriptions of the author are extraordinarily detailed; nevertheless he obviates great bulkiness and repetition, having introduced abbreviations for homological parts of the body and the extremities, which are also adopted on the plates. Moreover, the single species are not described one after the other, as is usually the case, but those belonging to the same genus are treated as a whole, their differences being treated in a diagnosis and by the help of synoptical lists (pp. 706–766) and indication of the plates where their specific characteristics are figured, the determination is greatly facilitated. As to nomenclature and synonymy, Giesbrecht is very rigorous in favour of priority, thus restoring even many older names to species described by Claus. A complete list of all described species, with complete indication of bibliography, is to be found on pages 676-705. The 54 plates contain 2300 figures, drawn masterly from nature by the author himself, and the first five plates, as mentioned above, give an idea of the variety of colour and form of appendages which exists even among these small marine organisms.

The systematical views and arrangements of Giesbrecht differ considerably from those of former authors. It is well known that the near relationship of the parasitical with the free-living Copepoda has been recognised already by H. Milne-Edwards; but it was Zenker who established systematically the two great groups of Natantia or Gnathostomata, and Parasita or Siphonostomata, a division which hitherto has been universally accepted. Giesbrecht points out the difficulties with which this division meets when one considers natural affinities, and thinks it impossible to adopt the manifold varieties of the construction of the oral appendages as a fundamental basis for classification. He proposes to divide the whole class into two great groups—the Gymnoplea and the Podoplea. The Gymnoplea are to be recognised by the following characteristics:—(1) chief body division occurring between the segment of the 5th foot-pair and the genital segment; (2) abdomen without rudiments of feet; (3) 5th foot-pair of the male transformed to an organ of copulation, genital organs asymmetrical; (4) heart in most cases present; (5) female carrying rarely ovisacs; (6) extremities plentifully articulated and provided with appendages. On the other hand, the Pleopoda are distinguished by (1) chief body division before the fifth pair of feet; (2) this latter rudimentary never serving as copulation organ; (3) male genital openings symmetrical; (4) heart always wanting; (5) female carrying always one or two ovisacs; (6) extremities rather scarcely provided with articulations and appendages. The great group of the Gymnoplea is further divided into two tribes—the Amphaskandria (male with symmetrical antennæ: family Calanidæ) and the Heterarthrandria (male on one side with prehensile antenna: families Centropagidæ, Candatidæ, Pontellidæ); to the family Centropagidæ are to be numbered all the Gymnoplea of fresh water. The description of the group of the Podoplea only takes up a small portion of the present monograph; therefore our author does not enter into a more detailed discussion of its classification, especially as not only all the littoral forms but most likely all the parasites belong to this group; he divides the group into two tribes—the Ampharthrandria (first pair of antennæ of the male symmetrical prehensile organs: families Misophriidæ, Mormonillidæ, Cyclopidæ, Harpactitidæ, Monstrillidæ) and the Isokerandria (antennæ of the male similar to those of the female; genital openings of the female dorsally situated: families Ontæidæ, Corycæidæ).

The rich harvest of pelagic Copepoda made by Capt. Chierchia on the three years' expedition of the Italian corvette, *Vettor Pisani*, enabled our author not only to describe a great number of new or incompletely characterised species of former authors, especially Dana's, but it gave him the possibility of explaining his views on the geographical distribution of the group, which we will only sketch with a few words, since a larger discussion of these views is impossible on account of the necessity to enter on the general conditions of pelagic life. According to Dr. Giesbrecht there are three great districts in the distribution of the pelagic Copepoda: two arctic ones, north and south, whose boundaries are at 47° N. and 44° S., and the intermediate one. The number of species belonging to this latter one is by far the greatest, almost 85 per cent. of all known species, whilst the north Arctic contains $5\frac{1}{3}$ per cent., the south Arctic $1\frac{2}{3}$ per cent. The faunistic differences between these three districts are greater than those of the three oceans; nevertheless there occur also in the Atlantic and in the Pacific species peculiar to each of them, especially in their northern parts. Pelagic Copepoda occur down to a depth of 4000 metres, and it seems that the boundaries of the above-named three districts stretch even down to these depths. Some species seem to live in very different depths, others exclusively near the surface; whether there are such that live exclusively in greater depths has not as yet been established. The character of the fauna depending more on latitude than on longitude it seems the determining causes of their geographical distribution must depend chiefly on physical agents such as light and temperature, but since the abyssal forms in the tropical parts of the Pacific are not identical with those of the northern and southern seas, which live on the same conditions of light and temperature, the difference in the three faunistic districts must be explained in part by still other causes. The distribution of other holopelagic animals seems to be identical with those of the Copepoda. According to Giesbrecht one seems to be justified in attributing the causes of the daily vertical wandering of pelagic animals to the influence of light, whilst the annual wanderings depend on temperature; besides these periodical wanderings some pelagic Copepoda seem to exist as eggs in greater depths and go slowly to the surface after their Nauplius stage.

I refrain from entering here into any greater details of the 831 large quarto pages of the volume lying before me, expressing only the hope that Dr. Giesbrecht may soon be able to publish his anatomical and embryological researches on the same group in a second volume. But as editor of the "Fauna and Flora," I may be permitted to congratulate the Zoological Station and science in general on the production of this volume, which answers fully to the programme of the whole series of monographs.

I may be permitted to state here that another big volume, treating of the Gammaridæ of the Gulf of Naples, and prepared by Prof. Della Valle, of the University of Modena, will soon follow the Copepoda of Giesbrecht, and will examine in a complete way these interesting crustaceans, including their embryology and anatomy. Splendid plates accompany also the work of Della Valle, and will give perhaps for the first time the varied and remarkable natural colouring of these creatures, generally only figured in outline and diagram by former authors.

After Della Valle's monograph a large, highly interesting, and most complete monograph of the Enteropneusta (Balanoglossus), by Prof. Spengel (Giessen), will be published. Most likely both these volumes will appear this year. A very large work on the Cephalopods by Dr. Tatta is in preparation, and its first volume, containing the classification and grosser anatomy, accompanied by most splendid plates, is nearly ready. A monograph by Dr. Bürger of Göttingen, treating the Nemerteans, is ready in MSS., and the Ostracods, by Dr. W. Müller, of Greifswald, are in the press; the Hirudinea by Prof. Apathy, of Klausenburg, have been in hand for five years, a botanical monograph treating the Rhodomeleæ, by Prof. Falckenburg, of Rostock, is near completion; Prof. Ludwig will contribute several volumes on the Echinoderms, of which most marvellous drawings by the artist of the Zoological Station, Mr. Mercoliano, have been prepared, and several other authors are engaged on other groups.

Some years ago a discussion took place at the British Association, whether it would be right to continue the grant for a table, and it was questioned whether the Zoological Station at Naples was really destined for research and not rather an educational institution; if it were necessary to strengthen the arguments in favour of the first statement, I think the enumeration of the monographs of the

"Fauna and Flora of the Gulf of Naples," either already published (Dr. Giesbrecht's monograph is the nineteenth volume published) or in preparation may convince also those who may still be doubtful in this regard.

Later, and in another article, I may be permitted to discuss some questions regarding another great publication of the Zoological Station, the *Zoologischer Jahresbericht*, a discussion which will touch some of the most vital questions of scientific organisation.

ANTON DOHRN.

BRITISH ASSOCIATION, NOTTINGHAM MEETING.

FURTHER information has been forwarded since the last issue of NATURE from Presidents and Recorders of Sections, of which the following statement is a summary:—

In Section B the following papers are promised, in addition to those already mentioned:—"The Action of Permanganate on Sulphites and Thiosulphates," by G. E. Brown and W. W. J. Nicol; "The Relation existing between Chromium and Certain Organic Acids, and some New Chromoxalates," and on "The Action of Phosphorus Pentachloride on Urethanes," by Emil A. Werner; "The Occurrence of Cyanonitride of Titanium in Ferromanganese," by T. W. Hogg; "Hydrogen Flame-cap Measurements, and the Adaptation of the Hydrogen-flame to the Miners' Safety-lamp," by Prof. Frank Clowes. A general statement of the arrangement of work in this Section appeared in last week's NATURE. The only probable alteration is the shifting of M. Moissan's demonstration to Friday, September 15, and of the Bacteriological discussion to Monday, 18.

An interesting paper is promised to Section E by Mr. Cope Whitehouse, a distinguished American citizen of New York and Cairo.

The presidential address in Section F, on "The Reaction in favour of the Classical Political Economy" will be mainly inspired by the idea that the principles and methods of the classical and orthodox economists have only been modified and supplemented, not displaced, by recent writers; and that both theoretically and practically there are signs of a reaction in favour of the older doctrines as against socialism.

The probable arrangement of work in Section H is as follows:—On Thursday, September 14, the President's address will be delivered, and a few papers on physical anthropology will be read. On Friday, 15, Dr. Hans Hildebrand, Royal Antiquary of Sweden, will read his paper on "Anglo-Saxon Remains, and the Coeval Ones in Scandinavia," and this will be followed by archæological papers. On Monday, 18, various papers will be taken. On Tuesday, 19, Dr. Munro will describe "The Structure of Lake Dwellings," and Mr. Arthur Bulleid will give an account of "The Recently Discovered Lake or Marsh Village near Glastonbury."

Papers which have not been already mentioned in Section H are—"Anthropometric Work in Schools," by Prof. Windle; "The Prehistoric Evolution of the Theories of Punishment, Revenge and Atonement," by Rev. G. Hartwell Jones; "Pin-wells and Rag-bushes," by Mr. Hartland; and "The Tribes of the Congo," by Mr. Herbert Ward.

The Local Secretaries wish to announce that the local programme and the list of hotels and lodgings are ready for issue, and may be obtained by application at the British Association Office, Guildhall, Nottingham, until September 9; after that, application should be made at the Reception Room, Mechanics' Institution. It may also be stated that the local committee has engaged the Theatre Royal for Wednesday night, September 20, when Mr. Wilson Barrett's Company will give the new play "Pharaoh." It is hoped that members will avail themselves of the invitation extended to them for this entertainment, and that it will induce them to remain in Nottingham, and take advantage of the excursions arranged for the following day. Other items worthy of mention are a special concert, which will be given by the Nottingham Sacred Harmonic Society on the Saturday night; and a garden-party, given by Mr. J. W. Leavers, in whose grounds some of the old rock-dwellings of Nottingham are to be seen. Geologists and naturalists will be interested to know that amongst the special local literature will be a little book entitled "Contributions to the Geology and Natural History of Nottinghamshire," which has been edited by Mr. J. W. Carr, M.A., with the assistance of local specialists.

FRANK CLOWES.

SCIENCE IN THE MAGAZINES.

SCIENCE makes a poor show in the September magazines. There are, however, one or two important articles which claim attention. In the *Contemporary Review* Prof. A. Weismann writes on "The All-Sufficiency of Natural Selection," his essay being an answer to two articles by Mr. Herbert Spencer directed against Prof. Weismann's views on heredity and natural selection. The essay is not merely controversial, but also a clear explanation of Weismannism. The following is the concluding paragraph:—

I hold it to be demonstrated that all hereditary adaptation rests on natural selection, and that natural selection is the one great principle that enables organisms to conform, to a certain high degree, to their varying conditions, by constructing new adaptations out of old ones. It is not merely an accessory principle, which only comes into operation when the assumed transmission of functional variations fails; but it is the chief principle in the variation of organisms, and compared to it, the primary variation which is due to the direct action of external influences on the germ-plasm, is of very secondary importance. For, as I previously said, the organism is composed of adaptations, some of which are of recent date, some are older, some very old; but the influence of primary variations on the physiognomy of species has been slight and of subordinate importance. Therefore I hold the discovery of natural selection to be one of the most fundamental ever made in the field of biology, and one that is alone sufficient to immortalise the names of Charles Darwin and Alfred Wallace. When my opponents set me down as an ultra-Darwinist, who takes a one-sided and exaggerated view of the principle discovered by the great naturalist, perhaps that may make an impression on some of the timid souls who always act on the supposition that the *juste-milieu* is proper; but it seems to me that it is never possible to say *a priori* how far-reaching a principle of explanation is: it must be tried first; and to have made such a trial has been my offence or my merit. Only very gradually have I learned the full scope of the principle of selection; and certainly I have been led beyond Darwin's conclusions. Progress in science usually involves a struggle against deep-rooted prejudices: such was the belief in the transmission of acquired characters; and it is only now that it has fortunately been overcome that the full significance of natural selection can be discerned. Now, for the first time, consummation of the principle is possible; and so my work has not been to exaggerate, but to complete.

Two articles of scientific interest appear in the *Fortnightly Review*. One, by Mr. W. Bevan Lewis, on "The Origin of Crime," deals with drunkenness, insanity, epilepsy, and similar affections in their mutual relationship to crime; in the second, entitled "The Climbing of High Mountains," Mr. W. M. Conway enthusiastically supports mountaineering in unexplored regions. Ordinary official surveys do not supply the detailed information with regard to buttress and fold in which resides the clue of mountain structure. It is for mountaineers to make up the deficiency.

In Mr. Conway's words:—

The Arctic and Antarctic regions remain for the future, and so do almost all the great mountain ranges in the world. The Alps alone are explored. The exploration of the Caucasus has been well begun, perhaps half done. Mr. Whymper has accomplished as much as one man can do in a season in the great Andes of Ecuador, but the Andes as a whole are little known. A good deal has been done in parts of the Rocky Mountains. Our New Zealand fellow-countrymen have boldly attacked the beautiful mountain fastnesses which belong to them. All these are hopeful beginnings, but the mountains of Central Africa and all the ranges of Asia are practically unknown. Thus the future of exploration is in the hands of climbers. The exploration of the Alps is a mere specimen on a small scale of the greater work which remains to be accomplished over areas incomparably vaster, and amongst ranges loftier and far more difficult than the Alps. . . . . Whilst the Himalayas have been in large part surveyed by the Indian Government, they are not, from a mountaineer's point of view, surveyed at all. No attempt has been made to give a true physical representation of the highest levels. The glaciation has been treated in the vaguest fashion and upon the ditch theory. From such work a mountain student cannot learn much. It was for this reason that I was tempted to make, in the year 1892, an expedition into the Karakoram Mountains, where are gathered together the mightiest group of glaciers in the world outside the Polar regions. The Hispar, the Biafo, and the Baltoro glaciers had for me the attraction of size as well as remoteness. The Hispar glacier was unsurveyed. The lower portions of the other two had been mapped by Colonel Godwin-Austen years ago, but their upper regions were unknown. The journey that I planned was duly carried out and resulted in the physical survey of some three thousand square miles of high mountain country. A map of the Central Asiatic mountain region lies before me as I write. It measures twelve by fifteen inches. On the same scale, the portion surveyed by me measures less than a square inch. This will give some idea of the amount of work that remains to be done in Asia by mountaineers.

The great difficulty in climbing at considerable altitudes lies in the diminished atmospheric pressure. Says Mr. Conway:—

It is more felt in hollow places than on ridges, more on snow than rocks, more in still air than a breeze, more in sunshine than under clouds or by night. It seems probable that the healthy human body can be accustomed to altitudes up to 18,000 or 19,000 feet. Above 19,000 feet a cumulative effect of discomfort is produced.

Mr. Conway and his party reached an altitude of 22,500 feet in the journey to the Karakorams referred to above, and he thinks an altitude of 24,000 feet may eventually be attained, but it will probably not be much exceeded.

Miss A. R. Taylor describes her sojourn in Thibet in the *National Review*.

Scribner's Magazine contains an interesting article on "The Tides of the Bay of Fundy," by Mr. Gustav Kobbé. Who has not heard of these tides, and wondered at their reputed magnitude? Statistics regarding the range are often so loosely stated that the following quotation is justifiable:—

At Grand Manan the fall is from twelve to fifteen feet, at Lubec and Eastport twenty feet, at St. John from twenty-four to thirty feet, at Monckton, on the bend of the Pelitcodiac, seventy feet, while the distance between high and low water mark on the Cobequid River is twelve miles—the river actually being twelve miles longer at high than at low water.

Under the title, "The First Artists of Europe," the Rev. S. Baring Gould gives, in *Good Words*, a well-illustrated description of the flint implements and tools, carvings on bone, horn, and ivory, sculptures, engravings, and sketches left by prehistoric reindeer hunters in caves, and beneath overhanging rocks in the valley of the Vézère, France. "The Story of the South African Diamond Fields" is told by the Rev. John Reid in the same magazine, and Mr. E. W. Abram contributes a biography of the Rev. F. O. Morris, whose volumes on "Birds" and "Butterflies and Moths" are known to all naturalists, and earned for him the name of "Gilbert White of the North."

"Bacterial Life and Light" is the title of an article by Mrs. Percy Frankland, in *Longman's Magazine*, in which the recent work that has been done on the bactericidal action of sunlight is brightly described.

NOTES.

MR. SCOTT ELLIOT has obtained a grant from the Government Grant Committee of the Royal Society for the purpose of exploring Uganda. We understand that his intention is to start from Mombassa and proceed direct to Lake Victoria Nyanza. After a short stay near the lake Mr. Scott Elliot hopes to leave for Ruwenzari, and to spend as long a time as his funds permit in exploring the botany, geology, and natural history of this mountain chain. Both Dr. Stuhlman and Dr. Baumann have been very lately in this neighbourhood, but still something of interest may be expected from Mr. Elliot's exploration.

THE works of the Cataract Construction Company at Niagara Falls are rapidly approaching completion. The tunnel is really finished, and so is the canal. The wheel-pits have had to be cut out of the solid rock. A power house is now being constructed to carry a travelling crane worked by an electric motor, the current for which will be supplied by a Westinghouse Engine and dynamo. The first of the three turbines of 5,000 horse-power has been made by the Morris Company, of Philadelphia, from designs by Faesch and Picard, of Geneva, and will be set up as soon as the electric crane is in its place. Prof. George Forbes, F.R.S., the electrical consulting engineer to the Cataract Company, has completed the plans for the electrical transmission, which will be by an alternating current. Vertical-shaft dynamos, each of 5,000 horse power, and capable of giving current in one or two phases, will be employed. It is hoped that the first of these dynamos will be built in about four months. The power will first be used at the new works of the Pittsburg Reduction Company, on the road towards Buffalo, for the production of aluminium. To hold the conductors, a roomy subway of concrete is being constructed. Cast-iron frames are built into the concrete, and brackets are fixed to them carrying insulators upon which the conductors will be supported. It will be seen from this that all the work is now well advanced, and a difficult enterprise is being brought to a successful termination.

THE exceptionally heavy cyclone which swept along the American coast on August 28 and 29, and was noted in our last issue, occasioned great loss of life and property both at sea and on land. The principal violence of the storm appears to have occurred in Georgia and South Carolina, and the fury of the wind completely swept down houses which were in the track of the hurricane. The storm was also accompanied by a tidal wave, which added immensely to the destruction on the sea-coast and on the islands in the main track of the disturbance. The wind is reported to have attained a velocity of 120 miles an hour, but much yet has to be learned from the numerous meteorological stations situated in or near to the storm's path. The cyclone was evidently an ordinary West Indian hurricane, which storms are not of uncommon occurrence at this season of the year; but it is unusual for these disturbances to maintain their full energy when they continue their course to the northward, and extend to regions well outside the tropics. This hurricane is said to have been experienced in the Bahamas three or four days before it broke with such fury on the shore of the mainland, and it is reported to have finally retreated out to sea as an ordinary gale. Just ten years ago a very severe storm traversed the south of England, and by means of ship's observations over the North Atlantic the disturbance was tracked from the tropics, along the coast of the United States, and eventually to our own shores. Doubtless the Weather Bureau of the United States will undertake a thorough and exhaustive study of the cyclone which has but just occurred.

ON the 28th ult. a hurricane passed over the more northerly of the Azores Islands, and caused great damage.

THE Rev. Leonard Blomefield, father of the Linnean Society, died at Bath on September 1, in his ninety-first year.

AN International Exposition will be held in the city of San Francisco, State of California, beginning on January 1, 1894, and continuing for six months. The general classification will be as follows:—Department A—Agriculture, food and its accessories, forestry and forest products, agricultural machinery and appliances; horticulture, viticulture, and pomology; fish, fisheries, products and apparatus of fishing. Department B—Machinery; mines, mining, and metallurgy; transportation—railway, vessels, vehicles; electricity and electrical appliances. Department C—Manufactures; liberal arts—education, literature, engineering, public works, constructive architecture, music and the drama; ethnology, archæology; progress of labour and invention. Department D—Fine arts: painting, sculpture, architecture, decoration. Department E—Isolated and collective exhibits. Mr. M. H. de Young is the Director-General and President of the Executive Committee, and all applications for space, &c., must be made to him, addressed Director-General, California Midwinter International Exposition, San Francisco, California, U.S.A.

IT is a custom to break clay vessels as a funeral rite in modern Greece, and there are proofs of the existence of similar customs among various Asiatic, African, American, and Australian peoples. Prof. N. G. Politis has investigated the origin of the practice (*Journal of the Anthropolgical Institute*, August), and has been led to conclude that it is connected with the purifications which now, as of old, form part of the funeral ritual. In a great many places, people on returning from a funeral or visiting a house of mourning, wash their hands, or are purified in some way with water, the vessels and towel used being afterwards destroyed. Prof. Politis is therefore of the opinion that the breaking of vessels is based upon two leading notions: (1) that everything used in the ritual of purification ought to be destroyed, lest the efficacy of the purificatory act be annulled through the profane use afterwards of things employed in its performance; and (2) that objects given to the dead must be destroyed, to guard against the possibility of their use for other purposes which annul their dedication to the dead, the belief being that all chattels must perish by fracture or mutilation of some kind in order to serve the purpose of a dead person, becoming through such mutilation unfit for living use.

IN "Midsummer Night's Dream," Shakespeare refers to "Russet-pated choughs many in sort, rising and cawing at the gun's report," but there appears to be a difference of opinion among ornithologists as to the bird so distinguished. So far back as 1871 Mr. J. E. Harting, in his "Ornithology of Shakespeare," interpreted the expression as meaning the gray-headed jackdaw, but the reviewer of the book in these columns remarked at the time that "without doubt the poet had in his mind the real Cornish chough, and the expression is quite accurate. 'Russet-pated' is having red *pattes*, or feet (*e.g.* the heraldic *croix pattée*, not a red *pate* or head), a feature equally inapplicable to chough or daw, while the red feet of the former are as diagnostic as can be." Mr. Harting returns to the subject in the *Zoologist* for September, and, in support of his view that the gray-headed jackdaw, and not the red-legged chough, is referred to, brings forward evidence to show (1) that the name *chough* was not exclusively bestowed upon the bird with red bill and red legs, but was also applied to the jackdaw; (2) that "pated" means "headed," and cannot be read "patted" for "footed"; (3) that "russet" is not red, though it may be reddish and is often used for gray; and (4) that the habit of the birds referred to by Shakespeare as "many in sort, rising and cawing," indicate a mixed flock of jackdaws and rooks, and not choughs and rooks.

WE have received from the *Deutsche Seewarte* vol. xv. of *Aus dem Archiv*, containing the report upon the work of that institution for the year 1892. In the department of maritime meteorology, especially, much activity has been shown, notwithstanding the serious obstacles experienced by the lamentable cholera epidemic. The various publications under this head include sailing directions for the Indian Ocean, daily synoptic weather charts for the North Atlantic (in conjunction with the Meteorological Institute in Copenhagen), and the collection of observations made beyond the sea. The observations received from ships alone amounted to an aggregate of 192 years, and these are used in the discussion of the meteorology of the ocean, which for this purpose is divided, according to the usual practice, into squares of ten degrees of latitude by ten of longitude. The department of weather telegraphy is also conducted with marked activity, and daily and monthly reports are regularly published. In addition to these operations, and the testing of numerous meteorological instruments and chronometers, many valuable discussions are undertaken, some of which are contained in the monthly *Annalen der Hydrographie*, &c. We shall refer later on to one or two of the special discussions included in the present volume.

As regards the behaviour of pathogenic forms in vegetable tissues, Russell states that, with but few exceptions, they were unable to exist for any length of time under these conditions. Lominsky, however, who conducted no less than 300 experiments on the vitality of anthrax, the typhoid bacillus, and staphylococcus pyogenes aureus in plants (Wratsch 1890), found that these organisms were not only able to exist but to multiply. Of especial interest was the behaviour of the anthrax bacillus when inoculated into agapanthus leaves. The bacilli grew into long threads, and at the end of seven days signs of spore formation were detected, both spores and threads being found later, not only at the point of inoculation, but within the healthy cells of the soft part of the leaf; moreover, after forty-two days' residence in the leaf, their virulence, as shown by inoculation into animals, was in no way impaired. Although saprophytic bacteria, as well as pathogenic forms, have not so far been found capable of inducing any disease in plants when artificially introduced, yet bacteria have been isolated which are especially pathogenic to plants. Amongst these may be mentioned the *B. hyacinthi* of Wakker affecting the bulbs and leaves of hyacinths, and the more recent *B. hyacinthi septicus* of Heinz, which affects also the flower clusters. The pear blight has been traced to a distinct bacillus, and Savastano describes a bacillus (*B. oleæ-tuberculosis*) causing destruction of tissue and formation of spaces in the tissue of numerous fruit trees, whilst closely allied to this form is a bacillus which produces tumours on the Aleppo pine. The list, although limited, is receiving constant additions, and there is a wide field open for researches on the bacterial diseases of plants, which may, moreover, be prosecuted without the intervention at present of the anti-vivisectionist!

HERR F. VON HEFNER-ALTENECK, in the *Electrotechnische Anzeiger*, makes a provisional statement about a system of electric control of clocks which appears likely to solve this much-attempted problem in a satisfactory manner. The main difficulty up to the present has been the necessity for a special wire system, central station, and attendance, the cost of which could not be defrayed by the limited public likely to require a luxury of this sort. Whenever, on the other hand, an enterprise was started with faulty mains and insufficient staff, the system was doomed to fail and to create a prejudice against the principle itself. All these difficulties are avoided by incorporating the control system with the electric light or power installation already existing. This is done by means of a clock invented by Herr von Hefner-Alteneck, which is placed in circuit like an ordinary incandescent lamp. It is kept wound up by the current, at an annual cost not exceeding that of one 16-candle lamp burning for ten hours, *i.e.* about 4*d.* In case of interruption of circuit, the clock will go about twelve hours independently of the current. The control is effected once a day by a momentary drop of the circuit potential by about 6 or 10 volts at 5 A.M., which has the effect of pointing all the clocks in the circuit at 5. The effect upon the lamps is inappreciable. The control can be performed by hand in the dynamo room, or automatically through the assistance of an observatory. The General Electric Company of Berlin proposes shortly to embody the system in its enterprises.

Messrs. Gauthier-Villars have issued their quarterly list of new publications.

We have received the Transactions and Proceedings of the New Zealand Institute, vol. xxv. 1892.

The report and proceedings of the Manchester Field Naturalists' and Archæologists' Society has been issued for the year 1892.

The Geological Survey of Alabama has issued a report, by Mr. A. M. Gibson, on the "Geological Structure of Murphree's Valley." The report deals particularly with the mineral resources of the region.

The University Correspondence College Press has published the fourth Intermediate Science and Preliminary Scientific Directory, containing the papers set at the examinations in July last, and the answers fully worked.

The Toynbee Hall Natural History Society recently organised an excursion to Jersey. Seventeen members took part in the expedition, and represented three sections—Botany, Geology, and Zoology. The whole of the coast and much of the interior was visited. At the monthly meeting of the Society, held Monday, September 4, many of the results of a fortnight's natural history work in the island were exhibited.

Two new volumes have been added to the Aide-Mémoire series edited by M. Léauté, and published by Messrs. Gauthier-Villars and M. G. Masson. "Accidents de Chaudières," by M. F. Sinigaglia, deals with the causes and prevention of boiler accidents, and M. H. Laurent, in his "Théorie des Jeux de Hasard," gives a number of problems connected with games of chance.

Messrs. John Bartholomew and Co., Edinburgh, have published a "Naturalists' Map of Scotland," showing (*a*) Faunal divisions and lighthouses; (*b*) Height of land and depth of sea; (*c*) Deer forests and salmon rivers; (*d*) Areas of moorland, hill pastures, and other uncultivated lands; (*e*) Areas of cultivated land. The map is excellently lithographed, and will doubtless be appreciated by the tourist as well as by the naturalist.

Mr. William F. Clay, Edinburgh, has published, as an Alembic Club reprint, the two papers by Cavendish, which appeared in the *Philosophical Transactions* under the title "Experiments on Air." The first paper appeared in 1784, and contains an account of Cavendish's researches into the composition of water; the second paper, published in the following year, contains the description of his discovery of nitric acid.

In 1891 a biological survey of parts of California, Nevada, Arizona, and Utah was conducted by the U.S. Department of Agriculture, Dr. C. Hart Merriam being in charge. The second part of the report on the results of this—the Death Valley Expedition—has just been published, and forms the seventh number of "North American Fauna." It consists of the special reports on birds, reptiles, batrachians, fishes, molluscs, insects, and the shrubs of the desert region, cacti and yuccas. The first part of the report, containing the narrative of the expedition, discussion of life-zones, and the list of mammalia, has not yet appeared.

Too great praise cannot be given to the authorities of the Natural History Museum for the excellent series of guide-books that are being issued from time to time by the various departments. The latest addition to this series is a guide to Sowerby's models of British Fungi in the department of botany, prepared by Mr. Worthington G. Smith. The Sowerby collection was acquired by the Museum in 1844, and consists of more than two hundred models made of unbaked pipeclay. Mr. Smith's description of the fungi should be widely distributed, for it will enable the public to distinguish easily the edible and poisonous species.

The benefits derived by science from the Smithsonian Institution are almost incalculable. Memoirs, monographs, and bibliographies of a most important character are distributed to private individuals and libraries with so free a hand that every one interested in the matters with which they deal must learn of their publication. A very important volume has recently been received from the institution; it is "A Select Bibliography of Chemistry," by Mr. Henry Carrington Bolton. The volume gives the titles of practically all the books on chemistry published in Europe and America between 1492 and 1892. It contains works in every department of both pure and applied chemistry. Academic dissertations, however, and theses, are not, as a rule, included, neither is the voluminous literature of periodicals. The works are arranged into seven sections as follows:—(1) Bibliography, (2) Dictionaries, (3) History, (4) Biography, (5) Chemistry, pure and applied, (6) Alchemy, (7) Periodicals. Section v. is more extensive than the other six combined. Besides pure chemistry, the book comprises works in every department of chemistry applied to the arts, but not to the arts themselves. In each section, with the exception of those of biography and periodicals, the titles are arranged alphabetically by authors. Altogether, 12,031 titles have been indexed, of which 4507 are in German, 2765 in English, and 2141 in French. In addition to the author's index, there is a subject-index which very considerably facilitates reference. For the conception of the bibliography and the completion of a stupendous work, Mr. Bolton deserves the thanks of all chemists. A debt of gratitude is also due to the Smithsonian Institution for publishing so useful a volume.

A further communication upon the manufacture of oxygen from the air by the agency of calcium plumbate, Ca_2PbO_4, the compound formed by lime with peroxide of lead, is contributed by Herr G. Kassner to the current number of the *Chemiker Zeitung.* Oxygen is now so important a commercial article that any new mode of advantageously preparing it upon a large scale must of necessity be of considerable interest. The success of the "Brin" method of isolating it indirectly from the atmosphere by the agency of barium peroxide has given rise to several attempts to discover some other substance capable of yielding oxygen of an equal degree of purity and under equally favourable conditions as regards cost of plant and working. Calcium plumbate would appear to possess several properties capable of rendering it an efficient substitute for barium peroxide, and Herr Kassner even claims for it a distinct superiority.

Whether this be indeed the case or not, can of course only be tested by actual working during a sufficiently long period of time. The method as described by Herr Kassner is briefly as follows. Calcium plumbate in the form of spongy porous pieces is first exposed to the action of moist furnace gases, which have been previously well washed, at a temperature not exceeding 100° C. The calcium plumbate under these conditions rapidly absorbs the carbon dioxide contained in the furnace gases, becoming thereby decomposed with formation of calcium carbonate and free peroxide of lead; that is to say, the acid properties of carbon dioxide are superior to those of lead peroxide, and so the former expels the latter from its state of combination with lime. This decomposition is unaccompanied by any change of form, the spongy pieces of material remaining precisely the same in shape and texture, like the pseudomorphs of mineralogy. The product of this first operation, when fully saturated with carbon dioxide, is transferred to a strongly constructed retort heated to redness, when oxygen is rapidly disengaged. The evolution of the oxygen is facilitated by leading superheated steam through the retort. When the peroxide of lead has yielded up most of its available oxygen, carbon dioxide commences to be evolved, and subsequently the issuing gas is pure carbon dioxide, which is collected separately. The carbon dioxide evolved during the intermediate phase is removed from the oxygen by allowing the gases to pass over a further quantity of calcium plumbate, which absorbs it entirely, allowing only pure oxygen to escape. The last phase in which pure carbon dioxide is evolved is carried on to completion, after which the residue is readily reconverted into calcium plumbate, for use in a subsequent operation, by driving a current of air through the retort.

IN addition to Kassner's process, above described, another has been patented by Peitz, in which instead of furnace gases pure carbon dioxide is employed. Le Chatelier has also recently published a paper upon the subject, in which, however, he does not appear to have been acquainted with the whole of Kassner's publications. Le Chatelier concludes that calcium plumbate gives up its available oxygen by merely heating it to a temperature of 200° higher than that employed in Brin's process in the case of barium peroxide, and that the heated residue absorbs oxygen from the air again much more rapidly than the latter substance. Kassner has already previously stated these facts, and now asserts that his indirect method possesses two great advantages over the direct one proposed by Le Chatelier, namely, that a lower temperature is required, and a consequent saving of fuel and wear of retorts effected, and that pure carbon dioxide is obtained as a very valuable by-product. The very fact, however, that there are so many possible modes of treating calcium plumbate, goes far to indicate that there is at least some ground for the proposal to employ it as a substitute for barium peroxide.

NOTES from the Marine Biological Station, Plymouth.—Last week's captures include the Polychæte *Eunice Harassii*, the Decapod *Pirimela denticulata*, and the Opisthobranchs *Hermæa bifida*, *Embletonia pulchra*, *Antiopa hyalina*, and *Thecacera pennigera*. The floating fauna retains its recent character, *Muggiæa atlantica*, *Evadne Nordmanni* and Ophiuroid *Plutei* having been especially plentiful. The larvæ of *Polygordius*, *Magelona*, *Nerine*, *Phoronis* and of several Crustacea Decapoda have been taken; and Müller's Polyclad larvæ have made their first appearance, although as yet only in small numbers. *Pilidium* has been scarce, but other Nemertine larvæ fairly numerous. *Doliolum Tritonis*, first recorded a fortnight since, has been represented by several specimens in almost every haul of the tow-nets. The following animals are now breeding:—The Polyclads *Eurylepta cornuta* and *Stylostomum variabile*, the Polychæte *Ophryotrocha* (in the aquarium), and the parasitic Isopod *Pleurocrypta Galatheæ*. The Gymnoblastic Hydroids *Perigonimus repens* and *Podocoryne carnea* are giving off medusæ.

THE additions to the Zoological Society's Gardens during the past week include a Malayan Bear (*Ursus malayanus*, ♀) from Malacca, presented by Mr. E. Sydney Wooduviss; a Feldegg's Falcon (*Falco feldeggi*) from Morocco, and two White-shafted Francolins (*Francolinus leucoscepus*, ♀ ♀) from North-east Africa, presented by Lord Lilford, F.Z.S.; two Common Buzzards (*Buteo vulgaris*) from Europe, presented by Mrs. Henry Goodbun; a Ring Ouzel (*Turdus torquatus*, ♂) from British Isles, presented by Mr. Samuel Radcliffe; two Sulphury Tyrants (*Pitangus sulphuratus*) from South America; a Chukar Partridge (*Caccabis chukar*) from North-west India, and a Bamboo Partridge (*Bambusicola thoracica*) from North China, presented by Mr. H. H. Sharland; a Land Rail (*Crex pratensis*) from British Isles, presented by Mr. W. Stanley; an Arabian Baboon (*Cynocephalus hamadryas*, ♀) from Arabia, and a Hairy Tapir (*Tapirus roulini*) from Columbia, deposited; two Sun Bitterns (*Europyga helias*, ♂ ♀) from South America, four Patagonian Cavies (*Dolichotis patachonica*, ♂ ♂ ♀ ♀) bred in France; an Elliot's Pheasant (*Phasianus ellioti*, ♂) from China, three Chilian Teal (*Querquedula creecoides*) from Antarctic America, and two Viscachas (*Lagostomus trichodactylus*, ♂ ♀) from Buenos Ayres, purchased.

OUR ASTRONOMICAL COLUMN.

THE TRANSIT OF VENUS OF 1874.—The reports and drawings of the New South Wales observers of this transit have already been published by the Royal Astronomical Society, so that the volume which we have received, containing the observations, published by authority of her Majesty's Government in New South Wales, cannot be looked upon as containing much that is new. Mr. Russell, the Government astronomer, under whose direction this work has been compiled, seems to have taken great pains in bringing it out, for besides a long introduction summing up the results, and separate accounts of each of the reports, the book is illustrated with several photographs and drawings, a frontispiece containing photographs of the observers, and is bound in a very elaborate cover. The value of this publication lies in the fact that each observer's record is published in full, and is accompanied by numerous printed diagrams, which help to make more clear the various descriptions of phenomena that were noticed. Passing over the observations of contacts, we may refer to some of the physical phenomena which seemed to have claimed attention. With regard, first, to the black drop, it seems that only those who were using telescopes of small aperture, 1½ to 2 inch, and low power eyepieces, saw it, while on the photographs not the slightest trace of it could be seen. The evidence, as far as the New South Wales observations go, shows, as Mr. Russell states, that "the black drop does not seem to be due to the atmospheric conditions, but rather to the imperfections of telescopes of small apertures and low power." The curious "faint tremulous shaking," as noticed at the times of the planet's ingress and egress, are put down to the temporary unsteadiness in the atmosphere. Three important phenomena which seem to have been generally observed were the rings of light and the halo seen surrounding the planet, and the ring of light round that part of the planet projected on the sky. Mr. Russell is of opinion that the atmosphere of Venus probably does not extend far enough to produce the observed phenomena of the halo, but, perhaps, a part of it could be attributed to the haze in the atmosphere caused by the forming of moisture at that time. The bright ring, described as very brilliant, was found to affect the chemicals more than the sun itself, as shown on the photographic plates; its brilliancy accounts for it being only seen on the limb not projected on the sun, and it is suggested that perhaps under favourable conditions this halo might be seen when the planet is lost in the sunlight.

THE PLANET VENUS.—Some time ago we noticed in these columns a short monograph on the "Planet Jupiter and his

Satellites," by Ellen M. Clerke. We have now before us a second one, entitled "The Planet Venus," in which the authoress lays before us in a pleasant manner a similar summary of the more important points connected with this planet's appearance. Commencing with a few words with regard to the position of Venus with relation to the other planets in the solar system, one is introduced successively to her changes of aspect due to her varying positions in her orbit, to the "silver crown" or halo produced by the refraction of the sun's rays round her globe, and to her rotation, general appearance, and polar caps. Her appearance at times of transit, and the phantom satellite, are then dealt with, the concluding chapter speaking of her in connection with the Star of Bethlehem. In this last reference is made to the "enhanced splendour with which she occasionally—once or twice in a century or so—shines at such times." That the planet does assume this increase of brightness, in addition to that due to her position, seems very doubtful, and the explanation here given to account for it depends on the luminous clouds theory suggested by the lectures on the liquefaction of gases by Prof. Dewar. The monograph is well worth a perusal, and should be widely read.

"Memoire della Societa," &c.—Among the contributions to these memoirs for the month of July will be found a detailed account of the late eclipse of the sun as observed from the Royal Observatory of Catania; a note by Millosevich giving some data with a map for the eclipses of May 28, 1900, and August 30, 1905; and the spectroscopic observations given in graphical form of the sun's limb, made at Palermo and Rome during the months of October, November, and December of 1891.

GEOGRAPHICAL NOTES.

In the September number of the *Geographical Journal*, Mr. Fred. Jeppe has a paper dealing in great detail with the Zoutpansberg gold-fields in the north of the Transvaal, illustrated by a new map of the district on a large scale, and by several photographs of characteristic scenery. The paper is historical as well as topographical, and contains an interesting account of the ancient workings in the Palabora region. The difficulty of orthography of place-names is referred to, several examples of alternative spelling being given, of which the series Li-Thaba, Lehlaba, Lechlaba, Lethaba, Letaba, Taba is characteristic. The district appears capable of great development when difficulties of transport are overcome by a branch from the Delagoa Bay railway.

Dr. R. Hansen contributes a paper to the last number of *Petermann's Mitteilungen* on the changes in the coastline of south-western Schleswig, with maps showing the coast as it existed in 1240, 1634, and 1892. These maps present a striking picture of the progressive diminution in area of the islands north of the mouth of the river Eider, especially Nordstrand, while those immediately adjoining the river mouth have been united with the mainland, and extended in area by the erection of dykes. As the islands have been inhabited from very early times, and protected to a certain extent by dykes, the process of coast-erosion has not been as continuous and gentle as would naturally be the case, but it has been a succession of artificial catyclasms—if the phrase may be used—brought about by exceptional storms destroying the sea-walls. In the old time each of these catastrophes was recorded amongst the islanders by the name of the patron saint of the day when it occurred.

Petermann's Mitteilungen also publishes a new map of Chitral and the surrounding districts of the Hindukush, by Mr. F. Immanuel, who describes the region in a short article.

Mr. H. M. Dickson spent the month of August on board H.M.S. *Jackal*, on behalf of the Fishery Board for Scotland, in carrying out a series of physical observations on the water between the Orkney, Shetland, and Faeroe Islands. This work was, to a certain extent, in concert with that being done by the Danish and Swedish Governments on the entrance to the Baltic and the neighbouring ports of the North Sea.

MEETING OF THE FRENCH ASSOCIATION.

The twenty-second meeting of the Association Française pour l'Avancement des Sciences was held this year at Besançon (Department du Doubs.), capital of the old province of Franche Comté. Few towns in France, even although small, are wanting in historic or antiquarian attractions, and in these respects Besançon has much to interest the antiquarian as well as the man of science, and therefore on its own merit is well worthy of a visit. The meeting of the French Association in this town not only enabled many to see it who otherwise would perhaps never have had occasion to do so, but owing to the facilities afforded, both by the municipality and by the civil and military authorities, practically everything interesting in the town and in the environs was liberally put within the reach of the members of the Association.

The meetings of the Association were held in the Lycée, which was built by the Jesuits about the commencement of the seventeenth century, and by reason of the great number of class-rooms afforded the necessary facilities for the meetings of the different sections for correspondence, &c.

The Association, although modelled on the lines of the British Association, has a slightly different scope, owing to the conditions which brought it into existence. It really commenced as the "Association Scientifique de France" in 1864, when it was founded by Le Verrier, but this subsequently to 1871 became combined with the Association Française pour l'Avancement des Sciences, the object of which was not only scientific after the mode of the British Association, but also aimed at reviving the study of science and of stimulating scientific research in the departments by bringing French scientific men together in the different principal towns throughout the country, enabling them thus to become better and more practically acquainted with France as a whole, and with the wishes, wants, and requirements of the populations. This patriotic object has been well kept in view, and the cordiality of the reception afforded to the Association wherever it goes shows how well its work is appreciated by the country. It would therefore follow that the study of the district visited forms an important part of the work of the Association, and that the "Excursions" are just as much sought after as in the meetings of the British Association.

The business usually commences with a general meeting, held either in the theatre of the town visited or other public building capable of affording the necessary facilities; in this case it was held in the theatre, a remarkable structure dating back to 1778, and inaugurated in 1784 by the Prince de Condé and his son, the Duc de Bourbon. On the stage facing the house was the table, at which sat the principal authorities of the town, civil and military, the president and principal officers of the Association, and ranged behind them the invited guests, notabilities, and chairmen of sections or committees, &c., evening dress being practically *de rigueur*. The business commenced by the Maire of Besançon reading an address of welcome to the Association, and of hearty sympathy with its objects. Then the president for the year, Dr. Bouchard, Membre de l'Institut and de l'Académie de Médicine, Professeur à la Faculté de Médicine de Paris, read his address, of which the following may be taken as the leading points. Having thanked the town of Pau for the reception given to the Association in 1892, and thanked the Maire of Besançon for the cordiality of his welcome, he defined the double object sought by the French Association's scientific progress, having for ulterior aim the greatness of their country. He paid a well-merited compliment to Besançon for its traditional love of learning and spirit of culture manifested in its celebrated men and scientific institutions. Turning then to the subject proper of his address, he expressed the desire to speak of the scientific movement and the position of scientific men at the present period, and in order to speak with competence he proposed to take his examples from the profession "which he cultivates, teaches, and practises," being justified in doing so by the fact of his having been called on to preside in his quality of a doctor. He then pointed to the wonderful development of scientific study at present, and stated that in the Faculty of Medicine of Paris 1200 students present themselves each year for the degree of M.D. (Doctorat en Médicine); of these 700 soon give up, while 500 persevere and attain their degree.

He pointed out that, whatever the causes, it is manifest that during the past fifteen years the number of students has been on the increase. He then entered on an analysis of the causes of this movement which extend to other branches of science.

"It has been said that the German schoolmaster was the conqueror at Sadowa; it was repeated after more recent disasters. It is false," but the "*mot fit fortune chez nous*," and the whole of France resolved to accept sacrifices equal in extent to those entailed by the defeat, in order to insure a national recovery. This sentiment dominated at the foundation of the French Association. Schools in every grade have been multiplied, as also new chairs. Their faculties have been created, at least for medicine, but have not given results expected of them. The real object sought was to retain in a certain number of university centres the crowd of students which encumber the Faculty of Medicine of Paris without profit for themselves or for it. "This encumberment seems not to have diminished at Paris, and our provincial faculties might without harm see their scholastic population trebled." As a matter of fact, the newly created chairs, laboratories, and faculties have in a remarkable manner multiplied sources of employment and created outlets for young men. It is certain that many have commenced working in order to make themselves positions in the teaching world. They have subsequently seriously taken up scientific study and disinterested scientific work. "Young men of science desire, and naturally so, that their work should be immediately remunerated. This is a novelty in our old university." These pretensions are to some extent legitimate, and the budget must provide for them, but the budget is beginning to resist, and the day is approaching when the State will only ask for, and will only accept, the absolutely necessary services, while on the other hand insuring to those who devote themselves to scientific instruction a honourable position and a satisfactory future.

"The public powers must become persuaded that instruction in every degree and in every direction of employment is and must be treated as a career."

As may be seen, we have reached a critical period when the plethora is become excessive, and a situation which has become painful has to be remedied somehow: "The raising of the standard of the position of men of science is one of the spontaneous consequences of progress, at once natural and necessary."

The applications of science carry with them certain advantages; one of these well calculated to entice generous natures, is the degree of esteem accorded to a profession. Certain professions enjoy more favour in given periods than others—military men during the First Empire, lawyers under the Restoration, engineers towards 1848, and under the Second Empire during the period of railway building. The turn of the doctor has perhaps come. "I am inclined to think so when I consider the extraordinary number of doctors who sit in the elected consultative bodies, and the important *rôles* that they play therein. Dr. Bouchard then cited their influence on Parliamentary legislation in the matters of vaccination, the use of antiseptics, and sanitation. In no way does the parallel progress of scientific dignity and public esteem manifest itself more strongly than in the matter of specialties. Knowledge is no longer encyclopædic. A doctor can no longer become learned but on condition of becoming a specialist. Surgeons have been the first specialists. They have extended to so many objects their fecund activity, and enlarged their domain to such an extent, that surgery, having absorbed everything about it, will soon cease to have a separate existence. It dismembers itself into specialties which multiply day by day. "I see approaching the day when there will be no longer either doctors or surgeons, and when there will exist for those who dedicate themselves to the art of healing a general pathology with general therapeutics, including amongst other things the laws and processes of operative intervention." Starting from this general fund of knowledge, doctors will classify themselves according to the natural groups of maladies to the study and treatment of which they may dedicate themselves. "It will be necessary that the State and the teaching bodies should comprehend, foresee, and provide for this evolution which is certain to be accomplished. It is necessary, above all, that those who dedicate themselves to the medical profession should receive a common and general solid instruction which will enable each one to work out later on, with fruit, his specialisation."

He then cited the position which oculists have attained in the public esteem. They have constituted a science. The art of the oculist has become ophthalmology, "the most brilliant, sure, and, I was about to say, most perfect branch of medicine." He considers in the same way the position attained by the dentist. In changing their titles oculists and dentists wish to mark the arrival of a new age, the accession of their arts to the real scientific period.

After a few words upon the position of men of science, Dr. Bouchard stated, as showing the wide field still open for modest efforts, that of the 36,000 communes of France 29,000 have no doctor. It is a field opened up for active and devoted work.

But neither ambition nor the satisfaction of worldy requirements, nor even the thirst for self-sacrifice suffice to explain the intensity of the movement which carries along to scientific occupations so many men belonging to the intellectual and moral *élite* of the nation. People go towards science because of its attractions and fascinations. If geometry can excite a very passion, why not the study of physical phenomena, the determination of biological laws? "Medicine has seductions which may raise a smile, but which all those who have dedicated their existence to it understand." To grasp the causes of disease, discern their modes of action, is the question which has been posed since the origin of medicine; it is the problem which for the last 2000 years and more has tormented the greatest intellects of the medical profession. These causes have been revealed to us for a great number of maladies by a man who was not a doctor. This revelation dates from but yesterday, and it is only since yesterday that we have been able to introduce into experimentation this factor up to the present unknown—the morbific cause (*la cause morbifique*). From this day dates the great reform in medicine. The modes of work of the old school were then compared with those of the new. They did what they could, what they would always have been obliged to do. They worked out the natural history of malady. They have seen the dawn of a new day. They have become acquainted with the *rôle* of the microbe in the universal transformation of matter, whether dead or alive, organic or inorganic, an idea so great and so fecund that each science in particular owes to it a part of its progress, while to it medicine owes its very renewal. Herein we have the true reason of this allurement which carries away so many liberal minds to the study of medicine. He then pointed out the parallel development of the study of septicism, and of the intimate relations of the various organs in their functions, and finished by indicating as the principal directing ideas of contemporary medicine, infection, diathesis, auto-intoxication, useful *rôle* of the internal secretions, nervous reactions, provoking and impeding healthy actions. He finished with some remarks as to the *rôle* of the Association—one of its great objects being to produce a scientific decentralisation. This decentralisation has been attained; it is in the minds while waiting to be affirmed by our Institutions. Meanwhile we continue our yearly peregrinations. "*Nous sommes en train de découvrer la France.*"

The address was remarkably well received.

The Secretary of the Association afterwards read a report on the work done during the last season, and the Treasurer rendered an account of the financial state of the Association, showing a balance in its favour of about 800,000 francs; Dr. Bouchard then declared the twenty-second session of their congress opened.

In the evening there was a reception held by the Maire at the Hotel de Ville, which was well attended.

At five o'clock on the same evening the bureaux or staff of officers of the different sections were fixed, and the agendas for the meetings to be held next morning. There were no addresses from the presidents of the sections.

Of the seventeen sections, Nos. 1 and 2 were devoted to Mathematics and Astronomy, 3 and 4 to Civil and Military Engineering, 5 and 7 to Physics and Meteorology, 6 to Chemistry, 8 to Geology and Mineralogy, and 9 to Botany. Section 10 dealt with Zoology and Physiology, 11 with Anthropology, 12 Medical Sciences, and 13 Agriculture. Geography was considered in section 14, Political Economy in 15, Pedagogy in 16, and Hygiene in 17. To all these sections a large number of important communications were made.

EXCURSIONS.

Sunday, August 6, Salins and Source of the Lison River.—Leaving at 6.30 a.m. by special train, Salins, situated about twenty-three miles south-south-west of Besançon, was reached at 7.30 a.m., after running through a hilly country showing the limestone formation of the Jura and fully cultivated. Salins is, as the name indicates, situated in a salt district, and the salt springs have been worked from very early if not prehistoric times. At present it is very much frequented on account of the medicinal action of the water. The situation is remarkable, being overlooked by bold heights which rise to altitudes of 620m. (Fort Belin) and 599m. (Fort St. André), the town itself being at an altitude of 354m. above the sea-level. The curative effects of the salt waters (the mother-liquors remaining after the separation of the salt) are mainly attributed to their remarkable richness in bromide of potassium 322 c. gr. per kg. of water. The natural salt springs worked contain 27 gr., 5 of chloride of sodium per kg., and yield about 13,000 h.lit. per day at 12° C.; they are also largely used for bathing purposes. The total production in salt of these works is about 6000 tons per annum.

Leaving Salins in carriages, the excursionists followed the road which winds up through the heights, and thus had an occasion of seeing the successive outcrops of the geological formations so characteristic of the district, Trias, Lias and Lower Jurassic, the roadsides affording plenty of fossils at different points. The "Col" having been reached, a high undulating district was attained showing the influence of altitude by the relative lateness of the crops, oats, &c., and their sparseness. The farmhouses also mark the vicinity of the high Jura in their form, high-pitched tiled roofs, massiveness, and overhangings, all evidencing relative comfort and prosperity. Having passed the bridge called the Pont du Diable, from the fantastic head sculptured on the keystone of the principal arch, and from the wildness of the gorge over which the road leads, the excursion reached about 11 a.m. the charming and well-wooded valley, deeply enclosed in bold and picturesque Jurassic escarpments, called Nans sous Ste. Anne. Here an excellent *déjeuner* was served under a tent, and in the afternoon a visit was made to the sources of the Lison, situated in a deep hollow, worn out in the Jurassic beds, and receiving from a certain height a cascade which disappears in one of those caves so common to all limestone formations.

The return to Salins was by a different route to that of the morning, but showing fine vistas, and displaying on all sides careful culture and abundant forest growth, which is mostly communal and worked with great care and skill. Along the road in the morning lay piles of timber showing diameters at the butts of 2 feet and 2½ feet, and lengths of 15 to 20–25 yards. Having visited the salt-works in the town, and seen the evidence of their antiquity in the succession of massive masonry constructions required from time to time for their preservation, dinner was served about seven o'clock in the hotel of the baths, and the party returned to Besançon.

Tuesday, August 8, Montbéliard and Belfort. — Leaving Besançon at 6.15 a.m., with the continued fine and warm weather of this wonderful season, the line ran along the Doubs River through a very picturesque and highly cultivated country. Montbéliard was reached about 7.50, when after a short halt the excursionists proceeded by steam tram to the works of Messrs. Peugeot Bros., at Audincourt. The visitors were divided in two series, A and B; the first were conveyed to the workshops of Valentigney (rolling mills, manufacture of springs and saws), and the workshops of Beaulieu (manufacture of bicycles); the last section, B, was conducted through the workshops of Terre Blanche (tools, hardware in general, coffee-mills, coach factory, electrical force plant, &c.). These works seem very active, well organised, and well in touch with the requirements of their markets, the tools manufactured by the firm having a high reputation for quality and cheapness. Everything indicated care and attention to the wants of the working people, and the general air of comfort and prosperity which was apparent in other parts of the department, and about Besançon, were here equally evident. Montbéliard was reached about twelve o'clock. There is little remarkable in it except a château of the fifteenth and sixteenth century, which now serves as barracks for the troops. The town is largely inhabited by a race of Protestants, descendants of the Anabaptists who sought refuge there from Friseland. There is also a Jewish element in the population, as indeed also at Besançon and Dijon, marked by the synagogue of a conventional style of architecture and the Hebrew inscriptions. Montbéliard is a very pretty busy town as regards manufactures, but the sewage arrangements *laissent à désirer*; this is to a certain degree intelligible from the fact of the town being situated on the canal which joins the Rhône and the Rhine at the junction of the rivers Allaine, Savoureuse, and Lizaine, at an altitude of 322m. As seen on the occasion of the visit, that is, during a season of great drought, there were evidently elements of typhoid fever, whether prevalent or not was not ascertained.

From Montbéliard to Belfort the line ran through a more rolling country than that in the immediate neighbourhood of Besançon. Belfort (pronounced by the French "Bay four") was reached at 2.15 (after an excellent *déjeuner* at Montbéliard, served in the gymnasium). Situated on the frontier, always a fortress of note, and now rendered celebrated by its splendid defence by Colonel Denfert during the campaign of 1870, its historic interest overpowers its other attractions. Special permission had been obtained for the excursionists to visit the château or citadel. This permission was largely taken advantage of by the excursionists, notwithstanding the somewhat abnormal heat of the afternoon sun. Guided by the officers of the Association and by those of the military service, the visitors were first conducted to the site of the splendid colossal lion which graces the western face of the fortress. Designed by Bartoldi, and executed in Vosges sandstone, it harmonises admirably with the lines of the ground and of the fortress structure. Whether the colour adopted is the best artistically is a matter for the sculptor and artists in general, but the lines are very fine, and the attitude of the lion very happy and expressive. The visitors were then conducted to the plateau, or flat roof, which crowns this part of the fortress, from which is discovered a splendid panoramic view of the surrounding country. An officer of the fort very obligingly gave a detailed description of the district surveyed, explained the position of the German army of siege, showed the line now forming the frontier, pointed out the various points of interest in view from the Ballons des Vosges in the north, to the Swiss Jura in the south, with the vast and fertile plain of Alsace lying between these points, here and there dotted with villages in the distance. One could not fail to appreciate the significance of the absence of a natural frontier line at this point, and at once to understand the vastness of the armaments which have to make good the security of a country so bounded.

A visit was then paid to the monument raised to the volunteers who fell during the campaign of 1870, and then a return was made to the principal square, in which the Town Hall is situated; here, at seven o'clock, dinner was served in a splendid hall ornamented with a set of very fine historic paintings illustrating events in the history of the place. A few and deeply felt words of welcome from the Maire, an equally short but expressive speech from the Préfect of the Department, and the dinner ended under the happiest of conditions for the visitors. A municipal band played during the dinner, and gave the members of the Association a *retraite aux flambeaux* to the station, whence Besançon was reached about 11.15 p.m.

Visit of the Citadel of Besançon, August 7.—By special permission the citadel was opened to the members of the Association in the afternoon of this day. The members, taking advantage of it, assembled at the Roman triumphal arch still preserved and known as the Porte Noire. Thence ascends the steep road conducting into the fort, and remembering that it may have been, or rather must have been, used by Cæsar when occupying and holding garrison in this city, one could not but feel a greater interest attaching to the various points presented by the guide. The structure of the fort is mainly due to Vauban, but of course is now somewhat out of date, but the position, taken in conjunction with the occupation of the neighbouring heights, is still very strong, and of great military value. From the parapet of the highest part of the fortress a splendid bird's-eye view is had of the town and its surroundings, while the windings of the River Doubs underneath, the variety of the culture clothing the neighbouring hills, the forts quietly looking out over all, and the hum of activity ascending the town, rendered the visit highly interesting, despite the abnormal heat and the climb to the lofty point of view. During the reconstruction of the fort by Vauban, he was obliged to demolish the church of Ste. Etienne, badly injured during the siege. The material was not, however, lost, and amongst other usages a tombstone, evidently of a bishop or an abbot of the Middle Ages, was used as a flooring for one of the sentry boxes or videttes which line the parapet or path running round the summit of the fortress. Other remains have been preserved, partly in the fort, and partly in the garden near the Porte Noire, the former site of a Roman theatre.

Final Excursion, August 11 to 13.—An accident, slight in itself but troublesome for the time, prevented me assisting at this excursion, which comprehended the source of the Loue Pontarlier, Neuchâtel, Bienne, Chaux de Fonds, and the Saut du Doubs, that is, an extremely dangerous and picturesque district on the frontier of Switzerland.

J. P. O'REILLY.

VARIATIONS OF LATITUDE.[1]

"ALL astronomy," says Laplace, "depends upon the invariability of the earth's axis of rotation upon the terrestrial spheroid and upon the uniformity of this rotation." He adds that "since the epoch when the application of the telescope to astronomical instruments gave the means of observing terrestrial latitudes with precision, no variations in such latitudes have been found which could not be attributed to errors of observation, which proves that since this epoch the axis of rotation has remained very near the same point on the terrestrial surface." ("Mécanique Céleste," tome v. page 22.) Admitting then the position of the earth's axis, and consequently the values of terrestrial latitudes, to be sufficiently invariable for the purposes of the astronomer, the question has been many times raised whether this conclusion represents more than a kind of first approximation to the truth.

As this subject, or something very much like it, was receiving more or less attention on the part of the ancient geographers two thousand years ago or more, we can hardly claim for it the charm of novelty. An important feature of the geography of Eratos Thenis, written between 200 and 300 B.C., was a critical review of the work of his predecessors. His map of the world, which represented the best and latest information of his day, had as a sort of base line, or axis of reference, a parallel of latitude drawn from the pillars of Hercules towards the east, passing north of the island of Sicily, across the southern part of the Peloponnesus, and eastward across the continent of Asia. The positions of many places with reference to this line differed very considerably from those assigned by his predecessors. At the time of Ptolemy—400 years later—it was known that the map of Eratos Thenis failed in many particulars to conform to the then existing order of things. The conclusion was obvious; evidently changes had taken place in the relative positions of a number of prominent places on the earth; nor were these changes simply the trifling fractions of a second with which men are struggling so valiantly in these degenerate days, but such satisfactory and tangible quantities as three, four, or five degrees. Ptolemy's geography furnished the basis for comparisons and discussions of this kind for fifteen hundred years. Some few of his latitudes, as that of Alexandria, were determined with such precision as was possible in those days, while the foundation of very many was little more than guess-work. Comparisons from time to time with later determinations brought to light discrepancies which served to keep the question open and to furnish material for speculation.

In this connection we shall stop only to mention Dominique Maria de Ferrare, who enjoys the distinction of having had as a disciple the illustrious Copernicus. This philosopher believed that the evidence showed conclusively a progressive change in the position of the pole, and that in time the torrid and frigid regions would in a manner change places.

So far as the latitudes of Ptolemy were concerned it was pointed out[2] that the discrepancies were in part due to the method employed in their determination—that of the gnomon which gave the altitude of the sun's upper limb, and consequently a value of the latitude too small by a quarter of a degree.

Two or three hundred years ago much interest was taken in this question. We find associated with it the familiar names of Tycho, Rœmer, Hevelius, Picard, Cassini, and many others. As greater accuracy in methods and instruments prevailed, it became evident that the rough positions of Ptolemy could not be employed with any confidence in discussions of this character. In connection with these more exact methods also a new phenomenon began to manifest itself, viz., changes of short period.

Christopher Rothman, a contemporary of Tycho, found systematic differences between the determinations of the latitude of his observatory made in summer and winter. Tycho's observations at Prague showed a like peculiarity. Rœmer also discovered it. He attributed it confidently to periodic changes in the position of the earth's axis, and hoped in time to give a complete theory of the same.

A memoir by J. D. Cassini,[3] published in 1693—200 years ago almost precisely—gives a very complete summary of the state of the problem at that day. After a detailed examination of the evidence he concludes:—"Notwithstanding all these apparent variations, we may say that not only has no extraordinary change in the altitude of the pole or in the meridian altitude of the sun occurred in recent times, but that the heavens have at all times occupied the same position with regard to the earth as during the past century. For there is reason to believe that all these variations which have been mentioned came from several defects which occur in observation." He then goes over in detail those sources of error which are so familiar to us—instrumental errors and defects in theory—one only having a somewhat unfamiliar appearance, viz., we may reasonably suppose that variations in the direction of the plumb line occur similar to those of the magnetic needle. Nevertheless he says it is very probable that from time to time small changes in the altitude of the pole actually do occur, but they are periodic in character and do not exceed two minutes in amount. Thus, instead of several degrees which were conceded by the astronomers of previous centuries, only a paltry two minutes was now allowed, but with improved instruments, with the discovery of aberration and nutation, and the perfection of the theory of refraction, even this modest allowance was gradually reduced to a vanishing quantity.

Meanwhile new arguments were found for a reconsideration of the question. Geology had taken its place among the sciences. In the investigation of the fossil remains of plant and animal life abundant evidence was found of a former temperate or subtropical climate within the Arctic circle. It was also evident that at one time considerable portions of Europe and North America had been covered with glacial ice. Laplace mentions the argument for a change in the position of the earth's axis, founded on the existence of the fossil remains of elephants in Northern Siberia, but believes that the discovery of the remains of one of these animals preserved in ice, the body of which was covered with thick hair, turns the argument against those who employ it (M.C. v. p. 20).

In the *Quarterly Journal of the Geological Society* for 1848 is found a communication from a mathematician and astronomer, Sir John Lubbock, on changes in climate resulting from changes in the earth's axis of rotation. He suggests a mathematical discussion of the problem in order to determine, as he says, "under what hypothesis a change of the position of the axis of rotation is possible or not." The President of the Association, Sir Henry T. de la Beche, in the annual address of 1849, deals at some length with this subject. Again, in 1876, we find Sir John Evans, then president of the Society, discussing the problem (*Quarterly Journal of the Geological Society*, 1876, p. 60). He describes with much detail the fossil remains found in Spitzenbergen and Greenland belonging to the Miocene, upper and lower Cretaceous, Jurassic, and other geological periods, all of which point to a former temperature much above the present. Thus, among the Miocene plants of Spitzenbergen Prof. Nordenshiäld mentions the swamp cypress, now found in Texas, siquoias of great size, limes, oaks, and even magnolias. So in the Lower Cretaceous period Prof. O. Heer distinguished seventy-five species, including ferns, Cycadeæ and Coniferæ, many of which are closely allied to species now found in sub-tropical regions. From these remains Prof. Heer infers that the climate of Greenland and Spitzenbergen during the Cretaceous period was very much the same as that which now prevails in Egypt and the Canary Isles. The existence of beds of coal, of mountain limestone formed of the remains of corals and bryozoa, and shells of marine molluscs, the remains of Ammonites, Nautili, and even a Saurian—the *Ichthyosaurus polaris*—all point in the same direction. While, as Prof. Houghton remarks, the arguments from the presence of Ammonites and Coalplants strengthen each other, the one demanding heat, the other light.

Sir John Evans sums up the arguments as follows:—"The three points which it appears to me are most important to bear in mind with regard to the article of flora are (1) that for vegetation such as has been described there must, according to all analogy, have been a greater aggregate amount of summer heat supplied than is now due to such high latitudes. (2) That there must have been a far less degree of winter cold than is in any way compatible with the position on the globe; and (3) that in all probability the amount and distribution of light which at present prevail within the Arctic circle are not such as would suffice for the life of the trees."

He afterwards supposes a hypothetical case of possible

[1] Address before Section A (Astronomy) of the American Association for the Advancement of Science, at Madison, Wisconsin, by Prof. C. L. Doolittle, of South Bethlehem, Pa., President of the Section.

[3] S'il est arrivé du changement dans la hauteur du pole au dans la Cones du Soleil? (*Memoires de l'Academie*, tome x. p. 360.)

elevation and depression, to which he invites the attention of mathematicians to determine whether it would not produce a change of 15″ or 20° in the position of the pole.

The invitation was duly accepted by Sir Wm. Thompson—now Lord Kelvin—and by Prof. G. H. Darwin. The former, by a process which he does not explain, convinced himself that a *vera causa* existed in the distortion of the earth, as shown by geological and other evidence, sufficient to produce large deviations in the position of the axis. To quote his own eloquent words, "Consider the great facts of the Himalayas and Andes, and Africa, and the depths of the Atlantic, and America, and the depths of the Pacific and Australia; and consider further the ellipticity of the equatorial section of the sea-level, estimated by Capt. Clarke at about one-tenth of the mean ellipticity of meridianal sections of the sea-level. We need no brush from the camel's tail to account for a change in the earth's axis; we need no violent convulsions, producing a sudden distortion on a great scale, with change of axis of maximum moment of inertia, followed by gigantic deluges; and we may not merely admit, but assert as highly probable, that the axis of maximum inertia and the axis of rotation, always very near one another, may have been in ancient times very far from the present geographical position, and may have gradually shifted through 10, 20, 30, or 40 or more degrees, without at any time any perceptible sudden disturbance of either land or water." (British Association Reports, 1876, Sections, p. 11).

Prof. G. H. Darwin has made this the subject of an elaborate mathematical investigation (*Phil. Trans.* 1877, p. 271). As the basis he takes the earth as we find it, assuming that the elevations of the continents and depressions of the ocean represent the kind and amount of distortion to which the earth has been subjected in the course of its past history. The mean elevation of the continents being about 1100 feet, and the mean depth of the oceans about 15,000 feet, it follows that in order to convert an ocean bed into a continent, or *vice versa*, an elevation or subsidence of 16,000 feet must have taken place. This would not, however, correctly represent the distortion of the earth, for the waters of the ocean flowing into the depressions would considerably modify the result. Taking into account the density of water as compared with the surface rocks, it appears that an extreme elevation of 16,000 feet from the bottom of the ocean to the surface of the supposed continent would be equivalent to an effective elevation of about 10,000 feet on a sealess globe. In case of a perfectly rigid globe, the only deformation which could take place would be that due to a redistribution of the surface materials. For a given elevation with a corresponding depression the maximum effect upon the position of the earth's axis would be produced when the elevations occurred in latitude 45° in two diametrically opposite quarters of the earth with corresponding depressions in the remaining quarters. In such a globe Prof. Darwin's analysis showed that the pole could never have wandered more than 3° from its original position as a consequence of the continents and oceans changing places. If, however, the earth is sufficiently plastic to admit of readjustment to new forms of equilibrium by earthquakes or otherwise, possible changes of 10° or 15° may have occurred.

This would, however, require such a complete changing about of the continents and oceans, with maximum elevations and depressions in precisely the most favourable places, as has certainly never occurred within geologic time. In fact, the evidence indicates that the continental areas have always occupied about the same position as now.

It would appear, therefore, that the geologist must give up this hypothesis of great changes in latitudes as a factor in the earth's development, unless, indeed, some other cause can be found of sufficient potency to produce the desired result. Such an agency is, perhaps, alluded to by Prof. Arthur Schuster in his address before Section A of the British Association a year ago (NATURE, 1892, Aug. 4, p. 327). He propounds this question: "Is there sufficient matter in interplanetary space to make it a conductor of electricity?" He adds that he believes the evidence to be in favour of this view; but the conductivity can only be small, for otherwise the earth would gradually set itself to revolve about its magnetic poles. If such an action were admitted, we must suppose the poles of revolution and magnetic poles would long since have been brought into practical coincidence, unless this consummation were frustrated by changes in the position of the latter.

However all this may be, the question before the practical astronomer is this—Have we any reliable evidence showing that progressive changes in the position of the pole are now taking place? If this question were submitted to a jury composed of twelve good men and true from the astronomical profession, the chances would be largely in favour of a verdict in agreement with Laplace's decision seventy years ago.

At the International Geodetic Conference held in Rome ten years ago, Mr. Fergola brought forward a plan looking to a systematic study of this and other questions connected with changes of terrestrial latitudes. This plan, which was favourably received, consisted in a scheme for simultaneous series of observations at pairs of observatories on nearly the same parallel of latitude, but differing widely in longitude. The instruments were to be prime vertical transits, and the same stars to be employed at each of the two stations. Several pairs of observatories were designated by Fergola as being favourably situated for the purpose. Among others, Washington and Lisbon, the difference of latitude being 11′ 7″, that of longitude 4h. 31m. It is understood that efforts in this direction were made at Washington, but the necessary cooperation at the other end of the line was not secured, and the plan came to naught. It has not come to my knowledge that the scheme was at that time seriously considered at any of the other points selected.

Fergola gave a tabular statement which at that time seemed to show small but progressive diminutions of latitudes in Europe and North America. This table, with some additions—the latter enclosed in brackets—is as follows:—

		°	′	″
Washington ...	1845	38	53	39·25
	1863			38·78
	[1883			38·94]
Paris	1825	48	50	13·0
	1853			11·2
	[1891			10·95]
Milan	1811	45	27	60·7
	1871			59·19
Rome	1810	41	53	54·26
	1866			54·09
Naples	1820	40	51	46·63
	1871			45·4[illegible]
Königsberg ...	1820	54	42	50·71
	1843			50·56
Greenwich ...	1838	51	28	38·43
	1845			38·17
	1856			37·92

In all these cases there is an apparent diminution during the present century. A similar tendency is shown by the observations of Peters, Gyldèn, and Nyrèn at Pulkowa, also by my own observations at Bethlehem since 1875. Instances are not wanting, however, where this diminution fails to manifest itself. Possibly most of the discrepancies shown here may be referred to periodic changes, the existence of which is no longer in doubt. It is by no means impossible or improbable that small local changes of latitude may occur due to slipping of the superficial strata of the earth's crust. That such lateral movements have taken place in times past in connection with mountain upheavals is, without doubt, true. That they are still going on in certain localities is probable; whether they are of sufficient magnitude to admit of measurement can only be determined by observation.

When we remember how few points there are on the surface of the earth, whose latitude was determined even no longer ago than fifty years, within one or two seconds of the truth, probably we should suspend judgment for the present with reference to the whole subject of progressive changes.

We come now to a phase of our subject with reference to which we can speak with some confidence, viz. periodic changes.

That in the case of a perfectly rigid earth, theory points to the existence of such a periodic change, completing its cycle in about ten months, has been long understood. In connection with the general problem of the motion of a free body under the action of any system of forces, the consideration of which was suggested by the problems of the solar system, we find the names of the leading mathematicians of the last century, d'Alembert, Segner, and Euler, not to mention others. It was the latter who, in 1765, in a work entitled "Theory of the Motion of Solid and Rigid Bodies," gave the equations the final form which Laplace declares seem to him the most simple which can possibly be obtained. (M. C.V. p. 284.)

The elegant form of these equations was due to the employment of the principle discovered by Segner, viz. that at every point of a body there are at least three principal axes of inertia at right angles to each other, which possess some very important properties. One of these properties is this—that if the body be set revolving about one of these axes which passes through its centre of inertia, and is understood by outside forces, it will continue to revolve about this axis for ever. If, however, it be started in its revolution about some other axis, the condition of things will be different.

In the first approximation to the solution of Euler's equations when applied to the earth, we meet with two constants of integration, whose values depend upon the position of the axis of revolution with respect to the principal axis of inertia (from which it can never differ greatly) at the instant which we take as the starting point of our integration. We further find that the presence of these quantities in our equations shows a revolution of the instantaneous axis of rotation about the principal axis of inertia. This rotation is in the same direction as the diurnal motion, the angular velocity y being expressed by the formula

$$y = \frac{C - A}{A} u$$

Where u is the velocity of diurnal rotation, C and A are the principal moments of inertia of the earth, the first with respect to the polar axis, the second with respect to an equatorial axis, the figure being regarded as that of an ellipsoid of revolution. The ratio

$$\frac{C - A}{A}$$

is found from the value of the constant of nutation, the degree of accuracy being such that the theoretical period of this rotation is known probably within one or two days. The value given by Oppolzer is 304·8 mean solar days. We shall assume it to be 305 days.

The angular distance between the two axes, evidently very small in case of the earth, can only be determined by observation, and will manifest its existence by fluctuations in the latitude having a period of 305 days. The first attempt to find by observation whether or not this movement was appreciable was by Bessel. This method was not well adapted to the purpose, and the result was negative or inconclusive.

The first quantitative determination which seemed worthy of confidence was made by Dr. C. A. F. Peters, of Pulkowa ("Recherches sur la Parallax des Etoiles Fixes," p. 146), in 1842. From a careful series of meridian circle observations carried on for thirteen months he found for the angle between the two axes ·071″ ± 017. Nyrèn followed with a careful discussion of the value given by the observations of Peters, Gyldèn, and himself with the same instrument. The results were ·101″, ·125″, and ·058″. Downing found from the Greenwich observations from 1868–77 ·075″ (*Monthly Notices, R.A.S.* March, 1892), while Newcomb found the somewhat smaller value ·04″ from the Washington prime vertical work.

These results are in reasonably good accord, and at first sight seem to show conclusively a real separation of the two axes, but as pointed out by Hall ("American Journal of Science," March, 1885, p 223), the form of the expressions for determining the quantity is such that an apparently real value will always be obtained. If we assume a uniform rotation of one pole about the other our equations will contain two unknown quantities, x and y, where $x = \rho \cos \xi \,.\, y = \rho \sin \xi$, therefore whatever values we may find for x and y . ρ will always have a real and positive value. This may, therefore, be nothing more than a function of the errors of observation. The true test was therefore to be sought in the agreement of the values of ξ when reduced to a common epoch. These were found to be quite discordant, so much so as to throw doubt upon the reality of the results. The truth, as we now understand it, being that Euler's theory, perfect as it is, does not apply without modification to the present problem—the earth not being strictly a rigid body. Doubts as to the absolute rigidity of the earth had been expressed by more than one investigator, and the matter was discussed in 1876 by Lord Kelvin (British Association Reports, 1876, Sections, p. 11), and in 1879 by Prof. George Darwin (*Phil. Trans.* 1879), in relation to the problems of precession, nutation and tidal action—the conclusion being that the rigidity of the earth is probably between that of steel and glass. The bearing of this upon the present investigation was first pointed out by Newcomb (*Monthly Notices*) *Royal Astronomical Soc.*, March, 1892), viz. that in consequence of the elastic yielding of the earth as a whole the period of this rotation would be lengthened.

Before considering this matter in detail, however, the exigencies of historical continuity require us to glance at some remarkable results of observation.

In the spring of 1884 Dr. F. Küstner, of Berlin, began a series of observations, the results of which were destined to awaken a widespread interest in this subject, or, perhaps more properly, to crystallise the interest which already existed. His original purpose was sufficiently modest. The great meridian circle of the observatory requiring some repairs, he proposed to employ the interval while it was out of service in making a limited series of observations with another instrument, the universal transit, according to the Horrebow-Talcott method for the investigation of the constant of aberration. His purpose was not so much that of deriving a new and definitive value of this constant, which should be entitled to rank with the excellent results previously obtained, as to test practically the applicability of the method to this purpose, and to acquire the experience which at a future time might lead to a favourable result in a more complete series. Possibly it would be overstraining a time-worn simile to compare the modest investigator with Saul, son of Kish, who, going forth to seek his father's asses, found a kingdom; but certain it is that his results were vastly more important and far-reaching than anything which he could have anticipated in his original programme. His observations, not numerous, but of the first order of excellence, led to a value of the constant of aberration which appeared to be wholly inadmissible. Many an investigator would have been discouraged with this apparent failure, and the world would have known nothing of it. Not so with Küstner. Instead of abandoning the experiment as a failure he set himself resolutely to work to discover the cause of the anomaly. After examining the various causes which might be supposed to have contributed to such a result, personal, instrumental, and refractional, he announced without hesitation that it was due to a change in the latitude itself, viz., that from August to November, 1884, the latitude of Berlin had been from 0.2″ to 0.3″ greater than from March to May in 1884 and 1885. This conclusion was materially strengthened by the examination of a considerable amount of collateral evidence, particularly Nyrèn's elaborate series of observations at Pulkowa from 1879 to 1882, employed by the latter in discussing the constant of aberration. This somewhat bold hypothesis naturally provoked much discussion, and many were sceptical as to its truth; but instead of resorting to polemics, and quoting the authority of Aristotle and the sacred Scriptures on the one side or on the other, means were promptly found for testing it. These comprised both a re-examination of old observations and new ones, undertaken for this express purpose. Among the latter were special series of latitude determinations extending over an entire year or more at Berlin, Potsdam, Prague, and Bethlehem, all by Talcott's method. All of these agreed most satisfactorily in showing the reality of the fluctuation during the years 1888, 1889 and 1890. But the final test which should determine whether the changes observed were due to movements of the earth's axis required observations to be carried on simultaneously at points differing widely in longitude. A latitude campaign instituted for this purpose was therefore entered upon in the summer of 1891, under the auspices of the International Geodetic Association, operations being carried on at Berlin, Prague, Strassburg, Rockside, San Francisco, and Waikiki.

Some of the results have been in possession of the public for several months, and they show in the most conclusive manner that we are dealing with a movement of the earth's axis.

A series of latitude observations was also carried on at Paris from December, 1890, to August, 1891; part of the time two different observers were employed using different instruments, their results agreeing almost exactly. (*Comptes Rendus*, 1892,

p. 895.) Science acknowledges no national allegiance, but it is interesting to note that this series fails to show any trace of the periodic change; considering the smallness of the quantity in question and the limited scope of the series this failure proves nothing *pro* or *con*. Yet Admiral Mauchez expressed the opinion that the fluctuations which the Germans had been attributing to changes of latitude were due to some other cause (*Comptes Rendus*, 1892, p. 862.) It is also noteworthy that the value of the latitude found at this time is 0·8″ smaller than given by the elaborate investigation of M. Galliot in 1879, in which he employed 1077 observations by ten different observers. (*Comptes Rendus*, vol. lxxxvii. p. 684.) In this discussion an annual period, having a semi-amplitude of 0·20″ manifested itself somewhat obscurely; but M. Galliot placed on record his opinion that this had its origin in some cause other than a change in the latitude.

We have seen how it came about that the reality of periodic fluctuations in the earth's axis was placed beyond dispute. As to the true nature and law of these fluctuations we should probably now be groping in darkness but for the services which Dr. S. C. Chandler has rendered in the way of solving the mystery. Before Dr. Chandler attacked the problem no one appears to have called in question the applicability of Euler's theory to the case of the earth. The impression was indeed quite general that the changes were for the most part of a fortuitous character, produced by precipitation of rain and snow, by ocean currents and aerial currents acting unequally in different hemispheres, and therefore in so far as they might manifest a periodicity, this would be annual in its character. As early as 1876 Lord Kelvin expressed the opinion that the causes were sometimes sufficient to produce change of half a second in the course of a year. (British Association Reports, 1876, Sections p. 11.) It seemed therefore beyond question that any periodic change must conform to the 305 day period of Euler, or to an annual period, or a combination of the two. The latter hypothesis was worked out very completely by Messrs. R. Radeau (*Comptes Rendus*, vol. iii. p. 568) and F. R. Helmert (*Astronomische Nachrichten*, vol. cxxvi. p. 217).

Matters were in this condition when in 1891 Chandler attacked the problem. The main features of this investigation are given in a series of seven remarkable papers published in the *Astronomical Journal*, written from time to time while the work was still in progress, and when, as a matter of course, the final result could not be known. Like Kepler, the author carries us with him along the successive stage of the investigation, we share with him his triumphs and disappointments, and rejoice with him when well-merited success crowns his efforts. As to his methods and purpose, these are given in his own words. "I deliberately put aside all teachings of theory, because it seemed to me high time that the facts should be examined by a purely inductive process that the nugatory results of all attempts to detect the existence of Eulerian period probably arose from a defect of the theory itself; and that the entangled condition of the whole subject required that it should be examined afresh by processes unfettered by any preconceived notions whatever. . . . The problem which I therefore proposed to myself was to see whether it would not be possible to lay the numerous ghosts in the shape of various discordant residual phenomena pertaining to determinations of aberration, parallaxes, latitudes, and the like, which had heretofore flitted elusively about the astronomy of precision during the century; or to reduce them to some tangible form by some simple consistent hypothesis. . . . It was thought if this could be done, a study of the nature of the forces as thus indicated by which the earth's rotation is influenced might lead to a physical explanation of them."

From May 29, 1884, to June 25, 1885, almost exactly the time covered by the observations of Küstner, at Berlin, Chandler was observing at Cambridge with the Almucantar. The resulting values of the latitude shared a progressive change, for which there seemed no explanation unless the change were that of the latitude itself. At that time this seemed too radical an hypothesis, so the results were printed as they appeared, leaving the explanation to the future. The close agreement of Küstner's results, the verification by the subsequent work at Berlin, Pulkowa, Potsdam, and Prague seemed to warrant the expenditure of the labour involved in a thorough investigation of the entire subject. He began with Küstner's work at Berlin, the vertical circle observations of Gyldèn and Nyrèn at Pulkowa, and the precise vertical observations of α Lyrae at Washington 1862–66. These agreed in showing a period of 427 days. The examination of observations of circumpolar stars at Melbourne, and of Polaris at Leyden, partially confirmed the result.

Next came the observations of Bradley at Kew, Wanstead, and Greenwich. Here a very puzzling phenomenon appeared, the period being only about one year, with an amplitude of nearly an entire second. In discussing the observations of Brindley at Dublin, made during the early part of the present century, an opportunity occurred to wrestle, and that successfully, with one of the ghosts before referred to, viz., the singular results which Brindley had obtained for the parallaxes of a number of stars, and which led to an interesting discussion between Pond and himself.

Thus series after series was analysed with results in the main encouraging, frequently puzzling, and sometimes disappointing. The law, if such existed, did not appear on the surface. The secret could only be discovered by an elaborate analysis of the material. Accordingly, forty-five different series, extending from 1837 to 1891, comprising more than 33,000 observations, were examined, from which an empirical law was deduced as follows.

The velocity of rotation of the pole was a maximum about 1774, the period being about 348 days. Since then the velocity has diminished at an accelerated rate, the period in 1890 being 443 days.

During the last half century the semi-amplitude has remained sensibly constant at 0·22″.

Only three of the forty-five series examined, and these among the least precise, intrinsically gave results contradictory of the general law. The next step in the process was to analyse the observations in a different manner, to discover whether the deviations from the provisional law were real, also in what manner the variations of the period were brought about. For this purpose the results were tabulated chronologically at twenty-day intervals, all reduced to the meridian of Greenwich. As a result the real nature of the phenomenon was most distinctly revealed, and was as follows.

The observed value of the latitude is the resultant curve arising from two periodic fluctuations superposed upon each other. The first of these, and in general the more considerable, has a period of about 427 days, and a semi-amplitude of about 0·12″. The second has an annual period with a range variable between ·04″ and ·20″ during the last half-century. The maximum and minimum of this annual component of the variation occur at the meridian of Greenwich about ten days before the vernal and autumnal equinoxes respectively, and it becomes zero just before the solstices.

As the resultant of these two motions, the variations of the latitude is subject to systematic alterations in a cycle of seven years' duration, resulting from the commensurability of the two terms. According as they conspire or interfere, the total range varies between two-thirds of a second at a maximum to but a few hundredths of a second at a minimum.

Accompanying the paper is a diagram showing the relation between this theory and the observations of the fifty-four years on which it is based. The agreement, at times almost perfect, at other times shows deviations, apparently systematic, which are perhaps due to imperfect knowledge of the constants, or to erratic deviations of meteorological origin.

Dr. Chandler finds the general outcome full of promise for the astronomy of precision, showing that observations are free from defects of a systematic character to a much greater extent than has heretofore been supposed.

As the results of which we have been speaking were announced from time to time they did not pass unchallenged. The reality of the 427-day period was very promptly called in question on account of its supposed conflict with dynamic laws.

Prof. Newcomb, who at first ranked as a sceptic, soon found a very plausible explanation by assuming that the earth is not a rigid body as required by Euler's theory. The question whether the earth as a whole should be regarded as a rigid body has long been more or less an open one. Certainly the waters of the ocean introduce an element of mobility, but the investigations of Lord Kelvin and Prof. Darwin of the bodily tides in a viscous spheroid when applied to the earth, gave very little, if any, evidence of yielding in case of the latter to external forces.

Laplace had discussed with negative results the effect upon the earth's motion of the mobility of the ocean. (M.C., tome v. p. 76.) Euler's equations had been modified by Liouville for the case of a body which is slowly changing its form from internal causes (*Liouville's Journal*, 2nd series, tome iii. 1858, p. 1), and these modified forms had been employed by Darwin in the discussion of the influence of geological changes in the earth's axis of rotation. (*Phil. Trans.* 1877, p. 271.)

No suspicion, however, seems to have entered the brain of any of these investigators that any modification of Euler's 305-day period would result either from the mobility of the ocean, or the elastic yielding of the earth as a whole.

Newcomb shows in a very simple manner how this result might follow (*Monthly Notices R.A.S.* March 1892, p. 336), for in consequence of this elastic yielding the pole of figure would be brought towards the pole of the instantaneous axis by the centrifugal force.

Let us call the undisturbed position of the pole of figure the fixed pole, the actual position at any instant the movable pole, and the pole of the instantaneous axis the pole of rotation. The movable pole is therefore constantly moving towards the pole of rotation, describing a sort of curve of pursuit; the instantaneous velocity of the latter about the former is that of Euler's period, but the effect of the motion of this movable pole is to diminish the velocity with respect to the fixed pole in the ratio of its distance from the latter to the distance from the pole of rotation.

Lord Kelvin remarks that this supplies a new and independent method of determining the effective rigidity of the earth. As will readily appear, in this distortion work is being done against resistance, and unless the earth be perfectly elastic, which is certainly not true of that part accessible to observation, the two axes would in time be brought into practical coincidence. The tidal action set up in the oceans would also tend to produce the same result. Apparently, then, the continued existence of this term requires a constantly recurring series of impulses.

Gylden remarks that the hypothesis of elasticity is not the only one which will explain the Chandlerian period. (Astronomische Nachrichten, Band 132, p. 193.) He also concludes as the result of a mathematical analysis that we must look for the impelling cause to concussions going on in the interior cavities of the globe.

Aside from the fact that these discussions are in need of explanation to an extent quite equal with that of the phenomenon itself, it is an open question whether any explanation is called for. We have no proof of the perpetuity of this term. We are in possession of no observations accurate enough to throw any light on this subject before the time of Bradley, nor can it be asserted that so small a coefficient has remained constant during the interval of 150 years; possibly it may be on the road to extinction.

As to the annual term, it seems to have no foundation in theory except as the result of meteorological causes, in which case we can hardly hope for more success in dealing with it than in predicting the weather on which it depends. For further improvement in our knowledge of this subject we must look to continued observation at a number of points carried on for this express purpose, and so conducted as to eliminate, if possible, all systematic errors. If, as seems probable, the coefficients—at least that of the annual term—partake of the erratic nature of meteorological phenomena, it will be necessary to keep this work up perpetually.

A plan is under discussion for establishing four permanent latitude stations on the same parallel of latitude, at intervals of 90° in longitude as nearly as may be. These will presumably be equipped with identical instruments of the most approved form, and the same stars employed at all of them. Until this plan, or some modification of it, is in working order—and probably for some time after—careful determinations at other points will continue to furnish valuable data, especially in settling the question of progressive changes, local or otherwise.

The instrument hitherto employed in special observations for this purpose is the zenith telescope. The possibility of determining latitude by measurement of the small difference of zenith distance of two stars properly situated—one culminating north, the other south of the zenith—was pointed out by Horrebow in his *Atrium Astronominæ* in 1732. (Wolf, "Geschichte der Astronomical," p. 608.) Possibly he may have made a practical application of the principle; if so, any account of it has escaped my notice. The method, however, was employed by Father Hell—otherwise not unknown to fame—in determining the latitude of his transit of Venus station at Wardoehume in 1769. He appears to have been unacquainted with Horrebow's previous suggestion, and determined his latitude in this way, as he says, from necessity.

The idea seems to have lain dormant until about 1834, when it was hit upon independently by Talcott in America, and Pond in England. The latter, in employing the zenith telescope—which had then been recently mounted at the Royal Observatory for the special purpose of observing γ Draconis—found that a fifth magnitude star passed the meridian thirty minutes later at nearly the same distance on the opposite side of the zenith.

By observing these two stars, reversing the instrument between them, he found certain advantages now well known to be inherent in the method. (*Phil. Trans.*, vol. cxxiv. p. 209.) Pond states that the same method may be employed with Altazimuths, and other portable instruments, but the communication appears to have attracted no attention, and apparently he made no attempt to develop it farther.

In striking contrast is the immediate success which attended the employment by Talcott of an instrument constructed to carry out this principle. The first practical application of it was in 1834, in the survey of the northern boundary of Ohio. (*Journal Franklin Institute*, October, 1838.) Its merits were very promptly recognised by the officers of the U.S. Coast Survey, where it received a number of modifications and improvements suggested by experience, making it practically the instrument which we have to-day. It was many years, however, before it came into use to any considerable extent on the eastern side of the Atlantic.

To America undoubtedly belongs the honour of practically introducing this important improvement in latitude determination.

But although Americans practically introduced the instrument to the world, it was reserved to the Germans to teach us how to use it. It is due in great measure to refinements and improvements devised by German observers and instrument makers that the probable error of a single determination is now ·12″ or ·15″, instead of three times these amounts, with which we were formerly satisfied. The essential features of this instrument are the micrometer and the level. Unless these are of a high degree of excellence first-class results cannot be obtained; especially is this true of the level, of which two are commonly employed with the best class of instruments. Only those who have experienced it are aware how difficult it is to procure levels of the necessary quality. Moreover, changes of form are liable to occur, rendering what was a good level worthless. The method so frequently employed by determining the value once for all, and continuing to use it for years without farther examination will not answer here.

This uncertainty of the level has led to devices for dispensing with it. One of these, which seems promising, is the floating Zenith telescope, invented by Fathers Hagan and Fargie. In this instrument the telescope, with its accessories, floats on the surface of a trough of mercury, the trail of the star as it crosses the field being recorded on a photographic plate, which may be measured at leisure. Possibly a way may be formed for making these exposures automatically, thus furnishing means for keeping a record continuous in so far as absence of daylight and of clouds will permit. With four stations established as described above, equipped with automatic instruments, data will be rapidly accumulated for settling the questions still remaining doubtful. It will not, however, be a work of merely one, two, or three, but of many years.

Is it too much to hope that within five or ten years we may see some such system as this in full and successful operation?

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

A PARLIAMENTARY paper has just been issued in which is given an abstract of returns furnished to the Department of Science and Art, showing the manner in which, and the extent to which the councils of counties and county boroughs in England and Wales, and the county councils, town councils, and police commissioners of police burghs are devoting funds to the purposes of science, art, and technical and manual instruction. The returns were made by these bodies in response to a letter sent to them in December, 1892, by the Education Department. Much of the information contained in them was noted in these columns on August 28 (p. 404). It is remarked in the present returns: "A noticeable feature with regard to the work of the county boroughs is that many of the councils have either erected or decided to erect, technical schools, or have taken over existing schools, for the purpose of supplying technical instruction under their direct control, to which they have decided to apply the whole of the funds at their disposal, which in some cases include the proceeds of a rate levied under the Act of 1889."

AT the Cambridge summer meeting, recently concluded, a lecture was delivered in the hall of St. John's College, on the late John Couch Adams, by Dr. Donald MacAlister. The lecture gained in interest from the fact that Dr. MacAlister was a personal friend of the late professor, and was in consequence able to supply many interesting details as to his life. This was particularly the case when speaking of Dr. Adams' early training. Many know that Adams was a sizar of St. John's, but perhaps few realise what a strenuous course of self education had preceded his election. He taught himself algebra when a boy at his father's farmhouse in Cornwall, and prepared himself for Cambridge at a country school and at the local Mechanics' Institute. A curious entry is to be found in Adams' diary for June 26, 1841, during his second year at Cambridge: "Went to Johnson's (the bookseller in Trinity Street) and read Professor Airy's report on the state of astronomical science," showing, as Dr. MacAlister explained, that his interest lay in that direction at that time as at a slightly later date. In the Tripos it is well known that Adams was as far above the second wrangler, in an exceptional year, as the second was above the wooden spoon. In a surprisingly short space of time, by 1846, Adams became celebrated for his discovery of Uranus, but it may not be remembered that for a short time he was a Professor at St. Andrews. On his return to Cambridge as the Lowndean Professor, he became associated with Pembroke College, as from 1853 he was a Fellow there. The University, as a memorial, has undertaken the publication of his works, and a monument of some kind is shortly to be placed in Westminster Abbey.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 28.—M. Lœwy in the chair.—On a typhoon of last year in the China seas, by M. H. Faye.—R. P. Chevalier, Director of the Meteorological Observatory of Zi-Ka-Wey, has sent an account of the terrible typhoon of October 7-10, 1892, which led to the loss of the British mail steamer *Bokhara*, to M. Faye. A close study of the phenomenon has revealed the fact that there was no high-pressure area for a distance of 600 to 1000 miles round the centre. This result is entirely in opposition to Ferrel's theory which asserts that every cyclone is surrounded by a high pressure area representing an anti-cyclone. P. Chevalier is also convinced that in low latitudes cirrus clouds form a constant indication of a distant typhoon. According to him, the centre of a typhoon and its direction are indicated by the point on the horizon whence the cirri appear to diverge, an observation which would locate the origin of typhoons in the region of low-latitude cirri, *i.e.* at a height of about 1200 or 1300 m., instead of at the surface of the earth, as often supposed. But P. Chevalier believes that the interior motions of the cyclone are represented by rectilinear convergent trajectories curved by the rotation of the earth, so that the air ascends in all the phenomena, except at the centre, where even he does not go so far as to deny the descending movement so clearly observed by Manille. He observes, however, that the foot of the cyclone was lifted above the surface at intervals, to descend in another portion of its track, and that it was independent of the nature of the ground, thus characterising itself as a phenomenon originating in the higher atmospheric strata exclusively.—Chrono-photographic study of the different kinds of locomotion in animals, by M. Marey.—In order to photograph different animals in motion, reptiles must be placed in a sort of circular canal where they can run on indefinitely, the chrono-photographic apparatus being placed above this canal. Fishes are made to swim in a similar canal filled with water illuminated from above, so that they appear dark on a light ground, or from above, so as to appear light on a dark background. The principal difficulty lies in causing the animal to move in its natural manner. Some interesting analogies may be observed between simple creeping and more complex movements. An eel and an adder progress in the water in the same manner; a wave of lateral inflexion runs incessantly from the head to the tail, and the speed of background propagation of this wave is only slightly superior to the velocity of translation of the animal itself. If the eel and the adder are placed on the ground, the mode of creeping will be modified in the same manner in the two species. In both, the wave of reptation will have a greater amplitude, and this amplitude grows more and more as the surface becomes smoother. In fishes provided with fins, and in reptiles possessing feet, there remains, in general, a more or less pronounced trace of the undulatory motion of reptation. The grey lizard, when photographed at the rate of forty or fifty exposures per second, exhibits this clearly, and also reveals the fact that the mode of progression by means of the feet is diagonal, and analogous to trotting. This gives rise to an alternation of convexity and concavity in the body on each side.—On a property of a class of algebraic surfaces, by M. Georges Humbert.—On the third principle of energetics, by M. W. Meyerhoffer.—The new principle recently added by M. Le Chatelier to thermodynamics, to the effect that every form of energy may be decomposed into two factors, one of which is of a constant magnitude, was enunciated two years ago by M. Meyerhoffer in the following form: everything which takes place in the world consists of processes in which the different capacities change their potential without changing in quantity, where the two factors are the capacity (*Inhalt*) and the potential.

GÖTTINGEN.

Royal Society of Sciences.—The *Nachrichten* (April to June) contains the following papers of scientific interest.

April.—H. Weber: Researches in the Theory of Numbers in the domain of Elliptic Functions, III. Th. Liebisch: The Spectrum Analysis of the Interference Colours of Biaxial Crystals. G. Bodländer: Experiments in Liquids containing Substances in Suspension, I.

June.—Lazarus Fletcher: Remarks on the Catalogue of the Meteorite Collection of the Göttingen University. F. Kohlrausch and W. Hallwachs: On the Density of Dilute Watery Solutions (with diagrams). F. Hultsch: The Approximate Values of irrational square roots given by Archimedes (with diagrams).

THE MECHANICS OF FLUIDS.

Hydrostatics and Elementary Hydrokinetics. By George M. Minchin, M.A., Professor of Applied Mathematics in the Royal Indian Engineering College, Coopers Hill. (Oxford: at the Clarendon Press, 1892.)

A WORK on this subject which should incorporate the latest developments has long been wanted; and Prof. Minchin has performed a very useful service in providing a treatise of a convenient size for purposes of instruction.

The first chapter starts with some general theorems on the distribution of strain and stress in the interior of a body, which to our way of thinking had better have been relegated to Chapters iii. or iv., by which time the student would be able to appreciate their importance. Mr. Minchin, however, justifies his method in eloquent language, but his simile of the danger of leaving uncaptured fortresses in the rear partakes of ante-Napoleonic ideas; as Napoleon proved it makes all the difference whether the foe is stationary or mobile.

We are pleased to see the author's practical protest against the banishment of the notation (we cannot dispense with the idea) of the Differential Calculus, traditional in our elementary treatises. A French schoolboy acquires a working knowledge of the Differential Calculus episodically, in the course of his studies of elementary algebra and trigonometry.

Mr. Minchin postulates at the outset a *perfect* fluid, that is a fluid devoid of viscosity. This is necessary when we come to the Motion of Fluids; but the theorems of Hydrostatics are true of all fluids, however viscous, such as tar, or even pitch; a fluid from its general definition is not capable of coming to rest till the *normality* of the stress has been attained.

The word *intensity* is prefixed by the author when it is wished to indicate that a stress is estimated per unit area; thus, for instance, 150 pounds on the square inch he calls the "intensity of the pressure." But this is contrary to our ordinary language, where "intensity" is never employed Mr. Minchin had better have adopted another word, "thrust," to express total pressure or push against a given area, leaving the words stress and pressure, as in common usage, to imply that they are estimated per unit area, square foot or inch, metre or centimetre.

This would not be the work of a modern college professor if the author did not explain at some length that the world has been calling things by their wrong names; thus it is maintained that the expression above "a pressure of 150 pounds on the square inch" is inaccurate, and should always be replaced by "an intensity of pressure of 150 pounds' *weight* on the square inch."

This is a counsel of perfection which a careful search would probably show is not always observed by the author himself; and it is invariably ignored and rejected by practical men, including his own engineering colleagues.

Thus Prof. Hearson, R.N., in a recent examination paper at the Naval College, Greenwich, asks for the calculation of the resistance of a train in "pounds per ton weight"; but his M.A. colleague would edit this into "pounds' weight per ton mass."

The Coopers Hill student will have to be as careful to recollect the expression appropriate for the class-room he is attending, as the Chairman of the House of Representatives in America, according to the story, in addressing the rival members of Illi*noi* and Illi*noise*.

The use of the word "weight" to designate only the accidental quality of a body due to its position on the surface of the Earth is much insisted upon by a certain school of our writers; but this temporary fad will soon pass away, we hope, as it seems to be tainted with the ancient heresy of the existence of bodies possessing positive levitation, such as the fire or inflammable air said to have been employed in Archytas's pigeon, or the rarefied dew with which Bishop Wilkins proposed to fill a number of egg-shells, and thereby fly in the air.

For instance, what is the weight of a ton (mass) of hydrogen; must we say that it is about—13 tons?

Prof. Oliver Lodge would banish the word "hundredweight" from our language; but what has he to offer the architect in exchange?

Pressures on foundations in architecture are most conveniently measured in cwt. per square foot, from the simple fact that the average weight of a cubic foot of brickwork is one hundredweight.

If the architect of the Tower of Pisa had made a calculation in accordance with the modern formula for the resistance of foundations in earth,

$$p = w\,h\left(\frac{1 + \sin\phi}{1 - \sin\phi}\right)^2,$$

in cwt. per sq. foot, at a depth of h feet in earth of density w cwt. per cubic foot, ϕ denoting the angle of repose of the earth, he would have found that his depth of 22 feet, with $w = 0{\cdot}8$ and $\phi = 22°$, would bear only 84 cwt. per square foot; while the pressure due to the weight of the tower mounted up to 145 cwt. per square foot.

Students owe a debt of gratitude to Prof. Minchin for having almost entirely banished the old-fashioned mystifications concerning

$$W = sV \text{ and } W = g\rho V;$$

and he very clearly points out that the pressure at a depth z in liquid of density ρ is not given by ρz gravitation units, but by $g\rho z$ absolute units.

But the introduction of the new term "*specific weight*" to designate what has hitherto been called the *heaviness* (or *density*) of a substance is to be deprecated, especially as the author is careful to explain that he does not mean *specific gravity* by *specific weight*.

But the German for specific gravity is *spezifische gewicht*, so that confusion is sure to arise; much the same as with the word *masseinheit*, which means unit *of measure*, and not *unit of mass*, as it has been incorrectly translated.

It is doubtful whether any advantage is gained by the introduction of absolute units into a statical subject; they are never used in experimental and practical work; but if the experimenter wishes to express his numerical results in a cosmopolitan form, he can multiply his gravitation results by the local value of g, as the last operation of all.

Unfortunately, in the C.G.S. system selected by scientific men, the units are so minute that they are only suitable for the most delicate phenomena of the physical laboratory, such as Capillarity; and numbers run very high in ordinary dynamical problems.

Millions of *boles* of impulse would be required to flick a sixpence across the counter; and the answer "millions," which Albert Smith said he received from the stoker when he asked how many degrees of temperature there were in the stoke-hold, would not be wrong if he had asked what pressure the boilers carried; "fifteen millions" might be the answer of the scientific stoker of to-day, trained in the use of the C.G.S. system.

Another banishment from this treatise to be grateful for, is that of "the whole pressure of a fluid on a curved surface."

If, however, this whole pressure is divided by the surface, we obtain the *average* pressure over the surface, a distinct mechanical motion, sometimes useful; with this resetting the "visionary problems of pure mathematics" on whole pressure might be allowed to survive, as some of them embody elegant geometrical applications.

Generally throughout the work Mr. Minchin has secured the assistance of his colleague Mr. Stocker, the Professor of Physics, for the experimental illustrations and diagrams, and we meet with many novel and ingenious experiments, for instance in the illustration of Boyle's Law in Fig. 57.

This gives a flavour of the Physical Laboratory to the book, and not that of the Engineering Theatre, except for the elegant geometrical treatment of the ine of Thrust in a Reservoir Dam. The Hydraulic Press of Fig. 7 could hardly serve to lift a girder of the Britannia Bridge, or squeeze a steel forging with a thrust of thousands of tons.

The equilibrium and stability of a floating body is illustrated in Fig. 49 by what looks like a champagne cork, and not by the cross-section of an ironclad or Atlantic steamer, with compartments bilged and full of water to illustrate the effect of petroleum or liquid cargo, or the unfortunate capsizing of the *Victoria*.

The diagram of a floating body in the ordinary mathematical treatise, where it is not like a cinder or a potato, but a vague idea of the cross-section of a ship, has the metacentre placed somewhere up the mast.

Prof. Minchin reduces this metacentric height to more reasonable figures, 5 or 6 feet; but even this is excessive, as H.M.S. *Prince Consort*, with a metacentric height of 6 feet, was a notorious bad roller; vessels of the greatest size are plying successfully with a metacentric height of under 1 foot; and we read a day or two ago of one of the largest modern steamers becoming unstable when being undocked.

The question of the stability of a ship involves the two antagonistic qualities of "stiffness" and "steadiness."

A "steady" vessel has a small initial metacentric height, and "stiffness" under sail is secured by making the metacentre rise rapidly as the ship heels.

The whole theory of the geometry of the ship is one of great mathematical interest; and the valuable compilation of all the best recent work on this subject, made by Sir E. J. Reed in his "Stability of Ships," deserves to be better known among mathematicians.

Chapter vi., on Gases, is one which will excite great admiration, from the way in which the leading parts of Thermodynamics are introduced; the most recent theories have been incorporated and illustrated numerically and experimentally; here the valuable assistance of Prof. Stocker is acknowledged. In this part of the subject we think that a simplification would be effected by pointing out that with the gravitation units employed in § 48, the quantity k in the equation $p = k\rho$ is the "height of the homogeneous atmosphere."

Hydraulic and Pneumatic Machines are carefully described and illustrated in Chapter vii. Fig. 71 of the Fire Engine is curious as illustrating the continuity of mathematical diagrams, as it might have been copied from the one given in Hero's Pneumatics B.C. 120, as invented by Ctesibius.

The hydraulic ram (*bélier hydraulique*), Fig. 73, is here attributed to Whitehurst, of Derby (1772). This will raise a protest in France, where Montgolfier is considered the inventor; but, on the other hand, Mr. Minchin gives Mariotte a half share in the discovery of Boyle's law.

Chapter viii., on "Molecular Forces and Capillarity," is very complete but rather formidable, as it does not shirk the difficult theories of Laplace on Molecular Pressure. The author must utilise in the next edition the scale invented by Mr. C. V. Boys, for drawing with accuracy the various capillary curves.

In the two hydrodynamical Chapters, ix. and x., there may appear some need for the use of the absolute units; but considering that the motion discussed is due to gravity, the only effect of a change from gravitation to absolute units is to remove g from the denominator of certain terms to the numerator of the remainder in the equations.

The use of hyperbolic functions would simplify the expressions on the last page of the book, in the discussion of Kelland's state of wave motion.

Judiciously selected examples are introduced in small sets, to illustrate the principles at easy stages; these are printed in smaller type, and the book is thereby kept within a handy size; at the expense, however, of the eyesight of some readers.

A. G. GREENHILL.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Palæozoic Glaciation in the Southern Hemisphere.

THE interest evinced in the above subject in so many quarters, and the evident ignorance of what has been done in the matter, is my excuse for asking space for some notes on my personal researches.

South Africa.—In July, 1872, while journeying through Bushmanland, at Mr. Niekerk's farm "Welgevonden," near Prieska, on the Orange River, I observed extensive accumulations of pebbles and boulders loosely piled, many of them striated, scored, and facetted—in fact, unmistakably ice-marked. One of the boulders I took to Cape Town, and deposited it in the South African Museum. This was the first discovery of glaciation in Cape Colony, and it attracted some attention at the time (*vide Cape Monthly Magazine*, &c.). While crossing Bushmanland, the boundaries of this conglomerate were jotted down, and they were delineated on my Sketch

Geological Map of Cape Colony, 1873, published by Stanford, London.

In the southern portion of Cape Colony no formation has excited so much interest, or proved so inscrutable a puzzle to the earlier geologists, as the zone of rock named "Porphyry" and "Trap Conglomerate" by the late A. E. Bain, "Trappean Ash" by Wylie, "Metamorphic Rock" by Pinchin, &c., and called "Bushman Graves" by the Boers. In Natal the same formation occurs, and Dr. Sutherland (of that colony) was the first to consider it as possibly of glacial origin, but he obtained no direct evidence to support that view.

As the names applied to this singular conglomerate were all misleading in my Sketch Geological Map of 1875, I named it the "Dwyka Conglomerate," on account of the excellent and characteristic sections exposed where the river of that name cuts through it.

While at Matjes Fontein, Cape Colony, in June, 1885, I obtained the first evidences of glaciation in this southern extension of the conglomerate among the loose pebbles, and more abundant evidence at Prince Albert, close by. In my report of 1886 to the Cape Government, the full extent of these conglomerates in South Africa is shown. Incidental reference and sections of the conglomerate occur in my report to the Cape Government dated 1879. The full extent of the conglomerate is also shown in my Sketch Geological Map of South Africa of 1887, published by Sands and McDougall, Melbourne.

Australia.—In 1887 I obtained indubitable evidence of glaciation in the conglomerate of Worragee, near Beechworth, Victoria, and placed well-striated pebbles and boulders in the local museum and in the Technological Museum, Melbourne. These were the first glaciated stones discovered in the palæozoic conglomerates of Victoria. Shortly afterwards, on visiting Bacchus Marsh and the Wild Duck Creek, I obtained abundant and unchallengeable testimony to the glacial origin of these conglomerates also for the first time, although their glacial origin was suspected thirty years ago by Sir A. Selwyn and the late Mr. Daintree. A paper on the subject was read before the Royal Society of Victoria in 1887, and several localities besides the above described. Another was read before the Australasian Association Meeting, December, 1890. A special report on the Wild Duck Creek conglomerate, prepared in 1891 for the Geological Survey Department, was published in 1892.

Tasmania.—In October, 1892, I once more encountered this remarkable conglomerate at the base of Mount Reid, near Strahan, and at an elevation of 3000 feet above sea-level. At this site it corresponds in a remarkable manner with both the Dwyka conglomerate of South Africa and the Wild Duck Creek conglomerate of Victoria. At the same time, and at a few miles' distance, I discovered around Lake Kora very extensive and marvellously well developed evidences of modern glaciation on a large scale. These discoveries were made public through the press at Hobart and at Melbourne in the beginning of November following, and a paper and plan has been submitted to the Royal Society of Melbourne, and read. The whole of my reports and maps have been supplied to the Geological Society, Burlington House. E. J. DUNN.

Melbourne, July 15.

Astronomical Photography.

LORD RAYLEIGH, in his letter (August 24), raises the interesting question of the adaptability of the plate to the object-glass. This is a novel idea, and I hope with him that we shall have the opinion of Captain Abney or some other authority on the question, or that it will be settled experimentally whether the use of an object-glass corrected for visual work will give, with properly prepared plates, results approximating those obtained with the photographic object-glass. In the case of Cambridge Observatory, there is already an object-glass of nearly twice the area of the proposed photographic telescope, so that it is quite possible as good results might be obtained with the Newall telescope as with the proposed one.

With the collodion process, where the curve of sensibility of the photographed spectrum had a well-defined summit, the photographic object-glass corrected for that part left very little to be desired. Now, the curves of sensibility of the different kind of plates vary extremely. We have long flat curves, or curves with two maxima; in fact, there is such a range now that it is a matter of surprise to me that any object-glass produces such good results as are obtained. Some years ago, after reading Dr. H. W. Vogel's "Photography of Coloured Objects," I thought that astronomers would be driven to the use of the only instrument that will use any and every plate—the Reflector; or if they would use the object-glass, that they would have to first find the most sensitive plate, and then make their object-glass to suit it. They should be made to suit each other. If this can be done by a variation of the photographic process without paying too dearly for it in the loss of sensitiveness, a great deal will be gained in many ways.

The great doubt in my mind is whether it is possible to get rid of the blue rays without the use of screens.

In any case, the object-glass can never properly use all the available light in the way the Reflector does, and it is a matter of extreme surprise to me that, notwithstanding the magnificent results obtained by the Reflector in astronomical photography astronomers still seem to prefer the expensive object-glass.

Ealing, September 11. A. A. COMMON.

The Greatest Rainfall in Twenty-four hours.

As a resident of Dehra Dún, I was interested in a paragraph at p. 297 of NATURE for July 27, 1893, saying that the *Indian Planters' Gazette* had recorded a rainfall of 48 inches at Dehra Dún on the night of January 24, 1893. As 48 inches is considerably more than half our average yearly rainfall (86 inches). I have looked up the official returns of the Meteorological Reporter to the Government of India. They give for the rainfall recorded at 8 a.m. on January 24, 1893, 0·26 inches only, 1·07 inch being the recorded fall on the same date at Mussoorie, on the hill range 11 miles off. I have examined the Dehra Dún rainfall records since January 1, 1867, and find that the largest amount recorded for any one day since that date is 11·60 inches, which is given for July 30, 1890. It is possible that the correspondent referred to wrote 4·8 inches, but even that amount, though not an uncommon fall for the monsoon season between June and September inclusive, would be a heavy fall for January. The highest recorded fall for any day in January is 2·84 inches on January 26, 1883.

J. S. GAMBLE.

Imperial Forest School, Dehra Dún, Aug. 22.

[The paragraph in question was taken from the *Ceylon Observer*. We append it as it appeared in our issue for July 27, together with a remark we made at the time.—ED.]

"If the *Indian Planters' Gazette* of 28 Jan., 1893, is correct, the following paragraph establishes a still higher record. On page 59 one reads: 'Our Dera Doon correspondent writes on January 24, 1893: last night we had 48 inches of rain, and all the hills are covered with snow. It is still raining.'" For this to have any scientific value, however, it must be known who were the observers, and by what means the rainfall was gauged.

Wasps.

OF late much has been written about the seasonal prevalence of wasps, and the mischief, in several places, wrought by them. May not, however, their use in keeping down many forms of insect pests be set off as some sort of palliative? Wasps are exterminators of aphides, and although the season has been favourable to insect-life, next to no damage has been done to the hop-bines or the corn or pulse crops of Worcestershire or Herefordshire by these latter pests—frequent destroyers of crops.

Is it suggestible that the excessive wasp prevalence is attributable in some measure to the abundance of their insect prey, just as has recently happened in Scotland, in the instance of the multiplication of the short-eared or "Woodcock" owl, owing to the plague of field voles? The owl is a winter immigrant, usually leaving in spring. "Nests in ordinary seasons are of rare occurrence in Great Britain, but owing to the vast increase of their favourite food—the field vole—these owls have not only arrived in increased numbers, but have remained and bred in Scotland all over the affected districts, laying from eight to thirteen eggs, and rearing large broods," instead of the few eggs these owls have hitherto been accredited with laying.

I am a fruit-grower. Much damage has this year been done to the fruit; not, however, by the wasp tribe, but by hungry birds, the fruit having even been attacked in an unripe state. According to my experience wasps do not become household pests till the falling-off of insect prey towards autumn.

Worcester, September 1. J. LLOYD BOZWARD.

THE AMERICAN ASSOCIATION.

MADISON, Wisconsin, at which the forty-second meeting of the American Association for the Advancement of Science was held, August 17 to 22, is a beautiful little University town, surrounded by clear, glacial lakes, and is the capital of the State of Wisconsin.

Several causes conspired to reduce the attendance of members at this meeting—the distraction of the World's Fair at Chicago, the financial stringency, and the remoteness of the place of meeting from the sea-board, where most of the members reside; but it was characterised by an earnest tone and an excellent quality of scientific work.

At the opening session the retiring President, Prof. Joseph Le Conte, gracefully introduced his successor, Prof. William Harkness, by remarking that while he represented geology, the president-elect represented astronomy: one the oldest, the other among the youngest of sciences; one concerned with the universe of space, the other with the universe of time; one with the law of gravitation, the other with that of evolution; one with the divine method of sustentation, the other with the divine method of creation of the universe.

Addresses of welcome followed by Major Corscot, General Lucius Fairchild, chairman of the local committee, and President C. K. Adams, of the University of Wisconsin, where the meeting was held. The latter gave a brief account of the use of the University, which has always made science prominent, and remarked that we are doubtless on the eve of wonderful discoveries. Physics and chemistry bring us near to the ultimate analysis of matter.

President Harkness, in replying, referred among other things to the British Association for the Advancement of Science as the pioneer of all such organisations. The reports of the condition of science at its organisation, over sixty years ago, were still valuable, and the early star catalogues made under its auspices were a valuable contribution to advancing science. The matter of nomenclature of electrical units was settled by the British Association, and the names, watt, ohm, ampere volt, now universally adopted, originated there.

Thursday afternoon was occupied with the addresses of the several vice-presidents, some of which will be printed in full in later numbers of NATURE. The generally high order of these addresses was matter of comment among members. The subjects presented were "Variations of Latitude," by C. L. Doolittle; "Phenomena of the Time Infinitesimal," by E. L. Nichols; "Twenty-five Years' Progress in Analytical Chemistry," by Edward Hart; "Training in Engineering Science," by S. W. Robinson; "Geological Time as indicated by the Sedimentary Rocks in North America," by C. D. Walcott; "Rise of the Mammalia," by H. F. Osborn; "Evolution and Classification," by C. E. Bessey; "The Biloxi Indians of Louisiana," by J. O. Dorsey; "The Mutual Relations of Science and Stock Breeding," by Mrs. H. Brewer.

The annual address by the retiring president, Prof. Joseph Le Conte, in the evening, on "Present State of Science on the subject of the origin of mountain ranges," was a masterly presentation of that difficult problem by an authority recognised as such throughout the world. The evening sessions were held in the capitol.

The mornings and afternoons of Friday, Monday, and Tuesday were occupied with reading of papers in the several sections.

On Friday evening Dr. Daniel G. Brinton lectured on "The Earliest Men," reviewing the latest discoveries of anthropologists. He localises the first habitat of man in southern Europe or northern Africa, or on the continuation of these latitudes in western or central southern Asia. Man seems to have been evolved *per saltum* from the highest anthropoid animal in the glacial, or possibly just before the glacial epoch, giving an antiquity of 50,000 to 100,000 years. The earliest men, so far as can be ascertained, walked erect, had full foreheads, red hair, and blue or gray eyes, were about of the same size and general appearance as now, perhaps were not even hairy, were kind to each other, social and artistic, had some sort of language, and knew how to make fire. Dr. Brinton's lecture, startling to the uninitiated by the boldness of his conjectures, derived added interest from his subsequent election as president of the association. As an anthropologist and anthropological writer, he has long occupied a front rank. He is a resident of Philadelphia, and a graduate of Yale in the class of 1858. He is a physician by profession, and a native of Chester County, Pennsylvania, where he was born in 1837.

The social features of the meeting were thoroughly delightful. The excursion to which Saturday was devoted deserves special mention, both for its pleasant relaxation and for the scientific interest of the region visited. Taking the cars of the Milwaukee and St. Paul railroad, a favourite tourist route, well known in England as well as in America, which is the only railroad leading to the scenic wonderland selected by the local committee as the best exhibit they could make to their guests, the association first passed through the remarkable driftless area ten or fifteen miles from the city. This is a region much studied by geologists as one which escaped the ice covering which extended over all the rest of the country during the glacial epoch. A ride of an hour and a half brought the train to Kilbourn city, where steamboats were taken up the Wisconsin river a distance of several miles, through "the dells" of that river, which are an expression of erosion resulting from a diversion of the Wisconsin river from its pre-glacial channel by the ice, and by the massive moraines which it produced. The rocks are Cambrian sandstone, and they show false bedding on a magnificent scale.

The places for several subsequent meetings of the association seem to be pretty clearly indicated, though no appointments were absolutely made. The new building of the Brooklyn Institute furnishes a good occasion for a meeting at Brooklyn next year, especially since that is now the only large city in the United States and Canada which has never been visited, if we except San Francisco, to which cordial invitations for a meeting in 1895 have already been received. The policy of the association, ever since its reorganisation at Buffalo in 1866, has been to hold decennial meetings at that city, so that 1896 also seems to be thus provided for.

The officers elected for next year are—president, Daniel G. Brinton, Media, Pa.; vice-presidents (Section A), Geo. C. Comstock, Madison, Wis.; (B) William A. Rogers, Waterville, Me.; (C) Thomas H. Norton, Cincinnati, O.; (D) Mansfield Merriman, South Bethlehem, Pa.; (E) Samuel Calvin, Iowa City, Iowa; (F) Samuel H. Scudder, Cambridge, Mass.; (G) Lucien M. Underwood, Greencastle, Ind.; (H) Franz Boas, Worcester, Mass.; (I) Henry Farquhar, Washington, D.C.; permanent secretary, F. W. Putnam, Cambridge, Mass.; general secretary, H. L. Fairchild, Rochester, N.Y.; secretary of the council, J. L. Howe, Louisville, Ky.; secretaries of the sections; (A) W. W. Beman, Ann Arbor, Mich.; (B) Benjamin W. Snow, Madison, Wis.; (C) S. M. Babcock, Madison, Wis.; (D) John H. Kinealy, St. Louis, Mo.; (E) Wm. M. Davis, Cambridge, Mass.; (F) Wm. Libbey, jun., Princeton, N.J.; (G) Charles R. Barnes, Madison, Wis.; (H) Alexander F. Chamberlain, Worcester, Mass.; (I) Manly Miles, Lansing, Mich.; treasurer, Wm. Lilly, Manch Chunk, Pa.

In Section A (Astronomy and Mathematics) most of the papers were as usual highly technical. The president of the section, Prof. Doolittle, carried on the line of thought presented in his annual address, by a paper on "Latitude Determination at Bethlehem in 1892–3," in which he stated that the fluctuation in latitude thus far noticed does not exceed about $0''.4$, being therefore less than fifty feet.

An interesting session was held at the Observatory, where the astronomer in charge, Prof. George C. Comstock, read a paper on "A Determination of the Constant of Aberration," and exhibited the instrument employed. It is a modified form of the Loewy prism apparatus, attached to a six-inch equatorial telescope. The principal element of the apparatus is a system of mirrors so placed before the objective as to reflect into the telescope images of the stars which are to be observed. As in the case of a sextant, images of two stars are simultaneously visible, and the apparatus may be regarded as a large reflecting instrument employed like a sextant for the measurement of the angular distance between stars, but subject to the limitation that the distances to be measured must differ but little from 120°. What is thus lost in range of application is compensated by the high degree of precision attainable with the apparatus, a discussion of nearly a thousand observations indicating $0''.3$ as the probable error for a single measured distance.

A preliminary discussion of a portion of these observations published in 1892 furnished for the value of the constant of aberration $20''.494$. A more rigorous discussion of the whole body of data, taking into account a possible annual variation in the amount of the atmospheric refraction, furnishes a value differing from the preceding by less than a thousandth of a second of arc; but this result cannot be considered definitive, since a comparison of the measured distances with values computed from the known right ascensions and declinations of the stars, indicates the existence in the observations of a systematic error depending upon the amount by which the measured distance differs from 120°. Reasons for supposing the error to be of subjective origin were indicated.

A discussion of the data thus corrected furnishes as the value of the constant of aberration $20''.445 \pm 0''.010$

As subsidiary results of this investigation it appears that the variation in the amount of the refraction from winter to summer is better represented by Regnault's value of the co-efficient of expansion of air, 0·003670, than by the values adopted in the tables of Bessel and the Pulkowa Observatory. Also, the observations are in very close agreement with the absolute values of the Pulkowa refractions, but indicate sensible corrections to Bessel's tables.

Section B (Physics) was prolific of good scientific work. The stereopticon views, with which vice-president Nichols illustrated his annual address, were a revelation of the astounding resources of photography in depicting phenomena of infinitesimal time, the alternating electric current with light and dark intervals clearly depicted, the flight of a bullet and its attendant sound waves shown as if at rest. Prof. Nichols does not think that he has yet reached the limit of these investigations. Although some of the exposures could only have been for a few millionths of a second, they were always long enough to secure a negative.

Of equal, if not superior, merit was the delicate and accurate apparatus for measuring expansions, exhibited by Profs. E. W. Morley and Wm. A. Rogers, called the Morley interferential comparator. In a paper read before the section, Prof. Morley explained that he had first described the proposed apparatus before a meeting of the Civil Engineers' Club of Cleveland, and afterwards at the Toronto meeting of this association in 1889. It was first used in a simplified form, in an experiment on the magnetic field, by Profs. Morley and Eddy, which was reported to the association at the Indianapolis meeting in 1890. The present paper was designed to recall to mind the principle of the apparatus and method, as an introduction to a paper by Prof. Rogers, in which several series of experiments with it were detailed, and also as a preparation for an exhibition of one of two forms of the apparatus which have been constructed for use in measuring expansions. These have been constructed by Prof. Rogers, with the aid of a small grant from the research fund of this association. It will measure the expansion of a metallic bar five or ten times as accurately as by old methods, being only limited by the accuracy with which temperature can be measured. It consists of two metallic bars, one of steel and one of bronze, with mirrors at each end, so adjusted that any change in adjustment is indicated by interference fringes of sodium light; 90,000 such fringes to the inch may be readily distinguished and counted. The mirrors are probably the most delicate ever made, being plain within two millionths of an inch, thus far exceeding in accuracy the best objectives of the largest telescopes.

Prof. Rogers followed with a paper in which he said that preliminary to the actual use of the interferential comparator in physical measurements, it was necessary to establish three points with great certainty.

(1) Does the value of the relative change per degree in the length of steel and bronze bars of metal, expressed in terms of wave lengths, remain constant? (2) Does the relative length of the two bars compared remain constant at the same temperature after the mirrors have been subjected to extreme temperatures? (3) Does this relative remain constant after the positions of the mirrors have been changed by means of the adjusting screws provided?

As a result of many experiments, an affirmative answer can be given to the two first inquiries. The change for each degree Centigrade was proved to be 38·31 fringes of sodium light for the steel bar, and 64·23 fringes for the bronze bar of Bailey's metal. When the observed differences in length were reduced to 5·1, the point at which the two bars had nearly the same length, it was found that the average probable error in a single comparison was about 0·72 of a single wave length, including all observations at wide ranges of temperature.

The answer to the third inquiry was less satisfactory, as occasional changes of ten fringes were obtained. The source of this error has, however, been found. In the new vacuo apparatus, the mirrors have been matched with great exactness. It was then found that the previous matching had been defective. Prof. Morley has computed the maximum effect of this error in changing the apparent relative lengths of the two bars, and has found it to be fifteen fringes.

The following are a few of the problems to the solution of which the apparatus has been applied:—

(1) The determination of the effect of slow changes in temperature upon the relative lengths of the two bars compared.

(2) The cooling effect of evaporation from a body of water placed near one of the bars.

(3) Measurement of slow changes in the bars compared due to the near presence of the observer.

(4) Measurement of the effect of obscure rays of heat stored in large masses of matter in close proximity.

(5) Measurement of the effect of flexure in changing the length of one of the bars.

(6) Measurement of changes in length produced by placing one of the bars in a magnetic field.

(7) Measurement of the heating effect of a current passed through one of the bars.

(8) Determination of the time required for the complete dissipation of a given amount of heat quickly applied to the bars.

(9) Proof that air is practically a non-conductor of heat.

(10) Determination of the value of 100 mikrons in terms of wave lengths of sodium and mercury fringes.

Prof. Alexander Macfarlane read a paper on the addition or composition of physical quantities, treating of one uniform method of the addition or composition of scalar quantities at different points, of vector quantities at the same point, of vector quantities at different points, of finite rotations round intersecting axes, of finite rotations round non-intersecting axes, and finally of screw motions. The screw motions compounded are not infinitesimal, but may be of any magnitude.

Profs. Macfarlane and G. W. Pierce contributed a paper on the electric strength of solid, liquid, and gaseous dielectrics, in which it was maintained that for a stratum of air or other gas between two parallel metal plates the electrostatic gradient when the spark passes is less the greater the distance between the plates; but for paraffined or beeswaxed paper this gradient is constant; it is also constant for paraffin oil or kerosene. The anomalous behaviour of the gaseous dielectric appears to be due to the greater freedom of motion of the molecules.

Mr. Joseph O. Thompson read a paper on "Fatigue in the Elasticity of Stretching." He remarked that attention was first called to the phenomena of elastic fatigue by Lord Kelvin some twenty-eight years ago. He used the elasticity of torsion in his experiments, and demonstrated that in some cases fatigue diminished the slide modulus as much as 6 per cent. Prof. Thompson's paper called attention to the fact hitherto undiscovered that a similar fatigue can be observed in the elasticity of stretching. Its influence in diminishing the Young's modulus amounted in these experiments to less than $\frac{1}{4}$ of 1 per cent. The wires used were 23m. long, and the metals in which the phenomenon was observed were silver, steel, and brass.

Messrs. F. Bedell, K. B. Miller, and W. F. Wagner contributed an elaborate mathematical paper on "Irregularities in Alternate Current Curves."

At the meeting of Section C (Chemistry) the notable feature was the presentation of Prof. Morley's final determination of the atomic weight of oxygen, giving results obtained by four distinct methods of investigation and with a degree of accuracy that will render this a final determination of this weight, correct to the third decimal figure. Three years ago Prof. Morley submitted a preliminary report, in which an account was given of the determination of the ratio of densities of oxygen and hydrogen as 15·884, correct within one part in four thousand. It has since been found that an accident happened to the apparatus during the last experiment of the series, which ought therefore to have been rejected. If this were now to be done, the value would become 15·882.

Two years ago some account was given of a series of determinations of the quantities of water produced from weighed quantities of oxygen and of hydrogen. Twelve experiments were made. In one the quantity of water produced was not determined, owing to accident. From the weights of hydrogen and oxygen consumed, the atomic weight of oxygen was found to be 15·8794, with a mean error of one part in 16,000 for a single experiment. From the quantities of hydrogen used and of water produced, the value obtained was 15·8792, with a mean error of one part in 7500 for a single determination.

At the present meeting, Prof. Morley reported the result of twenty determinations of the absolute density of oxygen, and twenty of that of hydrogen. The ratio of these densities found was 15·882.

If now the ratio of the volumes in which oxygen and hydrogen combine is substantially that found in these experiments, the atomic weight of oxygen computed from the densities would be 15·882 from the former series of determinations (or 15·880, if the correction is allowable), and 15·880 from the present series, we should then have :—

15·879, from ratio of H to O
15·879 ,, ,, H to H_2O
15·882 [or 15·880] ratio of densities (*a*)
15·880 from ,, ,, (*b*)

as the result so far of Prof. Morley's work.

But the later work of Scott has attained a high degree of excellence, and gives a value of the ratio of the volumes in which the gases combine, which is considerably higher than that used in this computation. Prof. Morley explained that he had himself published every experiment which he had ever made on this point, and that they had a mean error of only one part in 26,000. Since no source of constant error had yet been pointed out, he had great confidence in the accuracy of his own experiments. He, however, intended to make another series of determinations with the apparatus used before, and one with a new apparatus now constructing.

He also mentioned three other series of determinations which he is now carrying on; two are determinations of the absolute density of hydrogen, and one a determination of that of oxygen; in these a very small mean error is attainable.

Among the other papers which attracted special attention, were one on "The Constitution of Paraldehyde and Metaldehyde," by W. R. Orndorff and John White; and one on "Solubility of Lead Oxide in the normal tartrates and other normal organic salts, with observations on the rotary power of the solutions thus obtained," by L. Kahlenberg and H. W. Hillyer.

In Section D (Mechanical Science and Engineering) the number of papers was small, owing to the increasing tendency of engineers to support special technical associations.

Messrs. Wm. S. Rogers, S. W. Robinson, and J. Burkitt Webb contributed useful notes on different topics; while the secretary of the section, Prof. D. S. Jacobus, read three papers describing ingenious apparatus devised and used by him at the Stevens Institute of Technology at Hoboken, N.J.

Among the papers read, we note one by Prof. J. J. Stevenson on "the use of the term Catskill," in which he offered strong objection to the application of this term to the whole series of rocks from the Hamilton to the lower carboniferous, as has been recently advocated. Since the group is well defined below, and since the geographical term Catskill represents conditions which prevailed over an extended area only during the latter part of the upper Devonian period, Prof. Stevenson thinks that the term should be restricted as defined by Vonuxem.

Mr. J. A. Holmes gave an interesting description of a map and section of the stratified rocks of the coastal plain of southern North Carolina. Mr. William Hallock reported the results of further observations of temperature in the deep well at Wheeling, W. Va. Since 1891 this well has filled with water by leaking below the surface. Temperature determinations have been made in the water, which are practically identical with the determinations made when the well was filled with air two years ago, showing that there is not an appreciable circulation of water in a hole five inches in diameter. Down to 3200 feet the gradient is 1° F. to 81·5 feet, and near the bottom 1° F. to each 60 feet.

Dr. C. R. Van Hise, referring to the "character of the folds in Marquette iron district," called attention to the fact that what has been considered a synclinal is really a great synclinorium, having a nearly east-west axis, and having both the north and the south limbs pushed under, producing a complex fold with overturned minor folds, and comparable to some of those which Heim has described from the Alps.

Prof. C. D. Walcott exhibited beautiful specimens of trilobites which he had collected from the Utica shale of New York, on which the antennæ and legs were remarkably well preserved. Mr. F. P. Gulliver exhibited beautiful papier maché models, one of the sand plain at Newtonville, Mass., and a second showing the theoretical conditions at the time of its formation.

A paper entitled "Additional Facts Bearing on the Unity of the Glacial Period," was read by Prof. G. F. Wright, consecutively with one by Frank Leverett on "Changes of Drainage in the Rock River Basin in Illinois." The latter is important as affording means of estimating the amount of erosion in inter-glacial compared with that of post-glacial time. The wide pre-glacial channel of the Rock is followed to the Green River Basin near Inlet Swamp, when it is choked up by accumulations of drift. The change to the present course is located early in the glacial period, since the present valley can be shown to have been opened to about its present size and depth prior to the formation of the kettle moraine of the Green Bay lobe, the gravels which occupy the new course of the river being derived from the ice-sheet at the time the moraine was forming near the head waters of the river. These gravels are traceable up to the head of the moraine as a moraine-headed terrace. It is found that the post-glacial erosion in the river valley is only one-half that accomplished in inter-glacial time, and whereas the post-glacial erosion is mainly in gravel and sand, the inter-glacial erosion was mainly in rock strata. This seems to Mr. Leverett to warrant the use of the term epoch rather than episode to characterise these time relations.

Mr. Warren Upham, in his paper on "Tertiary and Quarternary Stream Erosion in North America," argued from stream erosion that an epeirogenic uplift preceded and probably produced the glacial epoch.

Section F (Zoology) having been severed from botany by the new amendment to the constitution, had comparatively few papers. The president, Prof. H. F. Osborn, carried on the line of thought contained in his annual address, by a paper on "The Mammals of the Upper Cretaceous," in which he proposed a system of classification and evolution materially differing from that of Prof. Marsh, which has so long held its ground. Prof. Osborn's studies lead him to more confidence in the belief that early forms are in many cases pretty highly specialised, and that evolution by degradation plays a pretty important part in biological investigation. This is quite in harmony with the statement of the president-elect of the association, Dr. Brinton, in his public address on "The Earliest Men," above noted, to the effect that the evolution of man appears to have been *per saltum.*

Section G (Botany) was organised at this meeting by division of the old section of biology, and considered a large number of papers of technical interest. Among the contributors were Arthur, Beal, Galloway, Dr. and Mrs. Britton, Barnes, Halstead, MacMillan, Coville. Dr. Britton discussed the question of nomenclature.

Probably the proceedings of the Botanical Club were even more interesting to botanists than those of the section, inasmuch as the club organised the Botanical Society of America with twenty-five charter members. Dr. Arthur exhibited to the club two very interesting pieces of apparatus, one a rotatory machine in which a germinating seed may be placed and subjected for hours or days to centrifugal force instead of gravitation. This apparatus gives the interesting result that the roots grow in the direction of the centrifugal force, and the leaves opposed to it. The other apparatus, called an auxanometer, shows by ingenious automatic action the rate of growth of plants.

Section H (Anthropology) furnished the largest number of papers. The first paper read in the section, by Washington Matthews, on "Songs of Sequence of the Navajos," was illustrated by reproductions of the songs by the phonograph. Dr. Joseph Jastrow gave an account of the system of psychologic investigation now pursued at the World's Fair. The recent discoveries resulting from excavations at the ancient argillite quarries on Geddes' Run, near the Delaware River, were presented by H. C. Mercer; and Ernest Volk made some observations in regard to the use of argillite by prehistoric people, as illustrated by explorations in the Delaware Valley. H. N. Rust read several papers on California Indians and implements. Prof. G. F. Wright presented a summary of the evidence in favour of the existence of glacial man in America, which commanded general attention because of the personal abuse to which Prof. Wright has recently been subjected. The subject was discussed at some length, and Prof. Wright's conclusions were violently attacked by Mr. McGee. Dr. Brinton read a paper on the "Mexican Calendar System," which he pronounces an anomaly, having no relation to the period either of solar or lunar revolution. It consists of 20 × 13, or 260 days. The 20 is a double digital basis. The 13 seems inexplicable.

The excursion of this section on Monday afternoon gave an opportunity to visit a group of effigy mounds just across Lake

Mendota, about four miles from the University. These mounds are of different shapes, that of the panther predominating, though birds and conical mounds are found also.

Section I (Economic Science and Statistics) had but few papers to consider, of which that of Mr. Henry Farquhar, on "Relations of Production and Price of Silver and Gold," introduced the topic of most general interest just now. The fallacy of attempting to maintain a silver standard of value was very apparent from the paper and the ensuing discussion. Improvements in metallurgy reduce the cost and vastly increase the production of silver, while that of gold remains almost stationary, there being really hardly any metallurgy of gold.

WM. H. HALE.

BRITISH ASSOCIATION.

NOTTINGHAM, SEPTEMBER 13.

THE meeting of the Association, which commences to-day, will take place mainly in the University College. In this building all the Sections, with the exception of the geographical, economical, and anthropological, will assemble. The Sections representing the experimental sciences will be accommodated in lecture theatres built and furnished for the express purpose of illustrating and demonstrating these sciences. Every convenience will therefore be afforded in the meeting rooms for the proper illustration of the papers which will be communicated. Further, the students' laboratories, which are in immediate connection with these theatres, will furnish most convenient exhibition rooms for the illustrative apparatus, specimens, and diagrams during the week of meeting, and when they are not required for illustration in the sectional room. The College will thus become the scientific headquarters during the meeting. It will in addition furnish convenient sectional committee rooms, sectional secretaries' rooms, anthropometric laboratory, ladies' boudoir, smoking-room, convenient retiring rooms, and a large luncheon buffet in the attached public lending library.

It is interesting to compare the facilities now offered for the meeting with those afforded during the preceding meeting in 1866 A temporary exhibition building then stood on the College site, and was used for the *conversazione*, but no suitable meeting rooms existed in the town for housing Sections A, B, C, D, and G. It will scarcely be necessary to inform those interested in the advancement of science that the existence of the College is due to the public spirit of the inhabitants of Nottingham, who willingly voted public money to establish the College, and who now mainly support it from the local rates. That such a bold experiment has met with the full success which it deserved, members of the Association who visit the town will learn and see for themselves. They will find that the initial success is leading to further success, and that outside support from the Government, from the Drapers' Company, and from other sources, is now being accorded with an ungrudging hand. It may be said with truth that since the Association last met in Nottingham, the town has become in a very important sense a centre for the advancement of science, and fully deserves all the encouragement and impetus which will be given to its comparatively new scientific work and aims by the visit of the Association.

It may be added that the Sections which meet outside the College are also accommodated in halls which were non-existent at the previous meeting in Nottingham, and that the evening meetings will take place in a large hall, which is new in the same sense. This will give some idea of the rapid progress which the town has made during the last quarter of a century.

Coming, as the Nottingham meeting does, between meetings at the venerable University towns of Edinburgh and Oxford, the status of the University College of the town must necessarily suffer by comparison. But it will be found that Nottingham, like the other provincial towns which have recently founded colleges in their midst, is by no means altogether at a disadvantage as regards its higher education by making a late start. In the matter of buildings and equipments it has benefited by the experience of its predecessors; and the absence of the fetters of an ancient *régime* has left it free to adapt its curriculum and methods to the needs of the present day.

With respect to the prospective work of the meeting, it may be stated that it promises to be fully up to the average in importance and in interest. A general statement of the papers to be brought forward, and of the discussions in the different Sections, has appeared in NATURE from time to time, and it is unnecessary to repeat the announcement of these in detail. It will be sufficient to remind members that in Section A questions of great interest and importance are put down for discussion; that in Section B, M. Moissan will d monstrate the preparation and properties of fluorine, a demonstration of absolutely unique interest, since this is the first opportunity afforded in this country of seeing these remarkable experiments. The President of the Section C and his colleagues have been most energetic in securing the attendance of distinguished foreign geologists, and in procuring numerous papers of local geological interest, in addition to discussions on points of general importance. In Section D, which will have the advantage of securing the special interest and support of the President of the Association, there will undoubtedly be good discussion of important biological problems, not only by Englishmen, but also by eminent continental biologists, who are guests of the town. In Section E the travellers are mustering in force, and will have their tales to tell of widely distant parts of the earth's surface; the photographs and paintings prepared in Antarctic regions will be of special interest in this section. Economic problems of the day are to be discussed in Section F. Section G will be represented by many eminent engineers, both English and foreign, and the experimental illustration of many of the papers, rendered possible by the meeting being held in a well-equipped engineering theatre, will add interest to the proceedings. In Section H the paper by Dr. Hans Hildebrand, and the description of the Glastonbury marsh village by Mr. Bulleid, with the discussions which they will undoubtedly give rise to, would, if they stood alone, constitute a tempting programme to anthropologists.

The efforts put forth in the town itself to make the gathering pleasant and successful will perhaps be best appreciated by reference to the local programme and maps now being issued to members. The townsmen have vindicated their character for hospitality by privately entertaining in their homes nearly 400 of their visitors. An ample list of hotels and lodgings, with a suitable map, has been issued for some weeks, some of the hotels binding themselves to a special tariff to members who engage their rooms through the local committee. The garden parties, excursions, and entertainments will be seen to have been so arranged as to leave no irksome leisure to be filled in by those who have done their duty to their Sections; and the scheme for privately engaging the Theatre Royal for the last Wednesday night will, it is hoped, justify by its success its boldness and originality.

With a programme of work of varied special and general interest and importance; with a universal desire on the part of the townsmen to do everything in their power to secure the comfort of their guests, and to afford pleasure and recreation to them; with the social element of the scientific gathering secured by the promise of attendance of men of science from all parts of our own country and from abroad; and, above all, with the promise of fine autumnal weather in a healthy, picturesque, and accessible town with most interesting surroundings, it will be strange indeed if the Nottingham meeting of 1893 should not become a record meeting, remembered by the pleasure and satisfaction it has given, if not by the largeness of the number who attend it.

FRANK CLOWES.

INAUGURAL ADDRESS BY J. S. BURDON-SANDERSON, M.A., M.D., LL.D., D.C.L., F.R.S., F.R.S.E., PROFESSOR OF PHYSIOLOGY IN THE UNIVERSITY OF OXFORD, PRESIDENT.

WE are assembled this evening as representatives of the sciences—men and women who seek to advance knowledge by scientific methods. The common ground on which we stand is that of belief in the paramount value of the end for which we are striving, of its inherent power to make men wiser, happier, and better; and our common purpose is to strengthen and encourage one another in our efforts for its attainment. We have come to learn what progress has been made in departments of knowledge which lie outside of our own special scientific interests and occupations, to widen our views, and to correct whatever misconceptions may have arisen from the necessity which limits each of us to his own field of study; and, above all, we are here for the purpose of bringing our divided energies into effectual and combined action.

Probably few of the members of the Association are fully aware of the influence which it has exercised during the last half-century and more in furthering the scientific development of this country. Wide as is the range of its activity, there has been no great question in the field of scientific inquiry which it has failed to discuss; no important line of investigation which it has not promoted; no great discovery which it has not welcomed. After more than sixty years of existence it still finds itself in the energy of middle life, looking back with satisfaction to what it has accomplished in its youth, and forward to an even more efficient future. One of the first of the national associations which exist in different countries for the advancement of science, its influence has been more felt than that of its successors because it is more wanted. The wealthiest country in the world, which has profited more—vastly more—by science than any other, England stands alone in the discredit of refusing the necessary expenditure for its development, and cares not that other nations should reap the harvest for which her own sons have laboured.

It is surely our duty not to rest satisfied with the reflection that England in the past has accomplished so much, but rather to unite and agitate in the confidence of eventual success. It is not the fault of governments, but of the nation, that the claims of science are not recognised. We have against us an overwhelming majority of the community, not merely of the ignorant, but of those who regard themselves as educated, who value science only in so far as it can be turned into money; for we are still in great measure—in greater measure than any other—a nation of shopkeepers. Let us who are of the minority—the remnant who believe that truth is in itself of supreme value, and the knowledge of it of supreme utility—do all that we can to bring public opinion to our side, so that the century which has given Young, Faraday, Lyell, Darwin, Maxwell, and Thomson to England, may before it closes see us prepared to take our part with other countries in combined action for the full development of natural knowledge.

Last year the necessity of an imperial observatory for physical science was, as no doubt many are aware, the subject of a discussion in Section A, which derived its interest from the number of leading physicists who took part in it, and especially from the presence and active participation of the distinguished man who is at the head of the National Physical Laboratory at Berlin. The equally pressing necessity for a central institution for chemistry, on a scale commensurate with the practical importance of that science, has been insisted upon in this Association and elsewhere by distinguished chemists. As regards biology I shall have a word to say in the same direction this evening. Of these three requirements it may be that the first is the most pressing. If so, let us all, whatever branch of science we represent, unite our efforts to realise it, in the assurance that if once the claim of science to liberal public support is admitted, the rest will follow.

In selecting a subject on which to address you this evening, I have followed the example of my predecessors in limiting myself to matters more or less connected with my own scientific occupations, believing that in discussing what most interests myself I should have the best chance of interesting you. The circumstance that at the last meeting of the British Association in this town, Section D assumed for the first time the title which it has since held, that of the Section of Biology, suggested to me that I might take the word "biology" as my starting-point, giving you some account of its origin and first use, and of the relations which subsist between biology and other branches of natural science.

Origin and Meaning of the Term "Biology."

The word "biology," which is now so familiar as comprising the sum of the knowledge which has as yet been acquired concerning living nature, was unknown until after the beginning of the present century. The term was first employed by Treviranus, who proposed to himself as a life-task the development of a new science, the aim of which should be to study the forms and phenomena of life, its origin and the conditions and laws of its existence, and embodied what was known on these subjects in a book of seven volumes, which he entitled "Biology, or the Philosophy of Living Nature." For its construction the material was very scanty, and was chiefly derived from the anatomists and physiologists. For botanists were entirely occupied in completing the work which Linnæus had begun, and the scope of zoology was in like manner limited to the description and classification of animals. It was a new thing to regard the study of living nature as a science by itself, worthy to occupy a place by the side of natural philosophy, and it was therefore necessary to vindicate its claim to such a position. Treviranus declined to found this claim on its useful applications to the arts of agriculture and medicine, considering that to regard any subject of study in relation to our bodily wants—in other words to utility—was to narrow it, but dwelt rather on its value as a discipline and on its surpassing interest. He commends biology to his readers as a study which, above all others, "nourishes and maintains the taste for simplicity and nobleness; which affords to the intellect ever new material for reflection, and to the imagination an inexhaustible source of attractive images."

Being himself a mathematician as well as a naturalist, he approaches the subject both from the side of natural philosophy and from that of natural history, and desires to found the new science on the fundamental distinction between living and non-living material. In discussing this distinction, he takes as his point of departure the constancy with which the activities which manifest themselves in the universe are balanced, emphasising the impossibility of excluding from that balance the vital activities of plants and animals. The difference between vital and physical processes he accordingly finds, not in the nature of the processes themselves, but in their co-ordination; that is, in their adaptedness to a given purpose, and to the peculiar and special relation in which the organism stands to the external world. All of this is expressed in a proposition difficult to translate into English, in which he defines life as consisting in the reaction of the organism to external influences, and contrasts the uniformity of vital reactions with the variety of their exciting causes.[1]

The purpose which I have in view in taking you back as I have done to the beginning of the century, is not merely to commemorate the work done by the wonderfully acute writer to whom we owe the first scientific conception of the science of life as a whole, but to show that this conception, as expressed in the definition I have given you as its foundation, can still be accepted as true. It suggests the *idea of organism* as that to which all other biological ideas must relate. It also suggests, although perhaps it does not express it, that *action* is not an attribute of the organism but of its essence—that if, on the other hand, protoplasm is the basis of life, life is the basis of protoplasm. Their relations to each other are reciprocal. We think of the visible structure only in connection with the invisible process. The definition is also of value as indicating at once the two lines of inquiry into which the science has divided by the natural evolution of knowledge. These two lines may be easily educed from the general principle from which Treviranus started, according to which it is the fundamental characteristic of the organism that all that goes on in it is to the advantage of the whole. I need scarcely say that this fundamental conception of organism has at all times presented itself

[1] "Leben besteht in der Gleichförmigkeit der Reaktionen bei ungleichförmigen Einwirkungen der Aussenwelt."—Treviranus, *Biologie oder Philosophie der lebenden Natur*, Göttingen, 1802, vol. i. p. 83.

to the minds of those who have sought to understand the distinction between living and non-living. Without going back to the true father and founder of biology, Aristotle, we may recall with interest the language employed in relation to it by the physiologists of three hundred years ago. It was at that time expressed by the term *consensus partium*—which was defined as the concurrence of parts in action, of such a nature that each does *quod suum est*, all combining to bring about one effect "as if they had been in secret council," but at the same time *constanti quadam naturæ lege*.[1] Prof. Huxley has made familiar to us how a century later Descartes imagined to himself a mechanism to carry out this *consensus*, based on such scanty knowledge as was then available of the structure of the nervous system. The discoveries of the early part of the present century relating to reflex action and the functions of sensory and motor nerves, served to realise in a wonderful way his anticipations as to the channels of influence, afferent and efferent, by which the *consensus* is maintained; and in recent times (as we hope to learn from Prof. Horsley's lecture on the physiology of the nervous system) these channels have been investigated with extraordinary minuteness and success.

Whether with the old writers we speak about *consensus*, with Treviranus about *adaptation*, or are content to take *organism* as our point of departure, it means that, regarding a plant or an animal as an organism, we concern ourselves primarily with its activities, or, to use the word which best expresses it, its energies. Now the first thing that strikes us in beginning to think about the activities of an organism is that they are naturally distinguishable into two kinds, according as we consider the action of the whole organism in its relation to the external world or to other organisms, or the action of the parts or organs in their relation to each other. The distinction to which we are thus led between the *internal* and *external* relations of plants and animals has of course always existed, but has only lately come into such prominence that it divides biologists more or less completely into two camps—on the one hand those who make it their aim to investigate the actions of the organism and its parts by the accepted methods of physics and chemistry, carrying this investigation as far as the conditions under which each process manifests itself will permit; on the other, those who interest themselves rather in considering the place which each organism occupies, and the part which it plays in the economy of nature. It is apparent that the two lines of inquiry, although they equally relate to what the organism *does*, rather than to what it *is*, and therefore both have equal right to be included in the one great science of life, or biology, yet lead in directions which are scarcely even parallel. So marked, indeed, is the distinction, that Prof. Haeckel some twenty years ago proposed to separate the study of organisms with reference to their place in nature under the designation of "œcology," defining it as comprising "the relations of the animal to its organic as well as to its inorganic environment, particularly its friendly or hostile relations to those animals or plants with which it comes into direct contact."[2] Whether this term expresses it or not, the distinction is a fundamental one. Whether with the œcologist we regard the organism in relation to the world, or with the physiologist as a wonderful complex of vital energies, the two branches have this in common, that both studies fix their attention, not on stuffed animals, butterflies in cases, or even microscopical sections of the animal or plant body—all of which relate to the framework of life—but on life itself.

The conception of biology which was developed by Treviranus as far as the knowledge of plants and animals which then existed rendered possible, seems to me still to express the scope of the science. I should have liked, had it been within my power, to present to you both aspects of the subject in equal fulness; but I feel that I shall best profit by the present opportunity if I derive my illustrations chiefly from the division of biology to which I am attached—that which concerns the *internal* relations of the organism, it being my object not to specialise in either direction, but as Treviranus desired to do, to regard it as part—surely a very important part—of the great science of nature.

The origin of life, the first transition from non-living to living, is a riddle which lies outside of our scope. No seriously-minded person, however, doubts that organised nature as it now presents itself to us has become what it is by a process of gradual perfecting or advancement, brought about by the elimination of those organisms which failed to obey the fundamental principle of adaptation which Treviranus indicated. Each step, therefore, in this evolution is a reaction to external influences, the motive of which is essentially the same as that by which from moment to moment the organism governs itself. And the whole process is a necessary outcome of the fact that those organisms are most prosperous which look best after their own welfare. As in that part of biology which deals with the internal relations of the organism, the interest of the individual is in like manner the sole motive by which every energy is guided. We may take what Treviranus called *selfish* adaptation—*Zweckmässigkeit für sich selber*—as a connecting link between the two branches of biological study. Out of this relation springs another which I need not say was not recognised until after the Darwinian epoch—that I mean, which subsists between the two evolutions, that of the race and that of the individual. Treviranus, no less distinctly than his great contemporary Lamarck, was well aware that the affinities of plants and animals must be estimated according to their developmental value, and consequently that classification must be founded on development; but it occurred to no one what the real link was between descent and development; nor was it, indeed, until several years after the publication of the "Origin" that Haeckel enunciated that "biogenetic law," according to which the development of any individual organism is but a memory, a recapitulation by the individual of the development of the race—of the process for which Fritz Müller had coined the excellent word "phylogenesis"; and that each stage of the former is but a transitory reappearance of a bygone epoch in its ancestral history. If, therefore, we are right in regarding ontogenesis as dependent on phylogenesis the origin of the former must correspond with that of the latter; that is, on the power which the race or the organism at every stage of its existence possesses of profiting by every condition or circumstance for its own advancement.

From the short summary of the connection between different parts of our science you will see that biology naturally falls into three divisions, and these are even more sharply distinguished by their methods than by their subjects; namely, *Physiology*, of which the methods are entirely experimental; *Morphology*, the science which deals with the forms and structure of plants and animals, and of which it may be said that the body is anatomy, the soul, development; and finally, *Œcology*, which uses all the knowledge it can obtain from the other two, but chiefly rests on the exploration of the endless varied phenomena of animal and plant life as they manifest themselves under natural conditions. This last branch of biology—the science which concerns itself with the external relations of plants and animals to each other, and to the past and present conditions of their existence—is by far the most attractive. In it those qualities of mind which especially distinguish the naturalist find their highest exercise, and it represents more than any other branch of the subject what Treviranus termed the "philosophy of living nature." Notwithstanding the very general interest which several of its problems excite at the present moment I do not propose to discuss any of them, but rather to limit myself to the humbler task of showing that the fundamental idea which finds one form of expression in the world of living beings regarded as a whole—the prevalence of the best—manifests itself with equal distinctness, and plays an equally essential part in the internal relations of the organism in the great science which treats of them—Physiology.

Origin and Scope of Modern Physiology.

Just as there was no true philosophy of living nature until Darwin, we may with almost equal truth say that physiology did not exist as a science before Johannes Müller. For although the sum of his numerous achievements in comparative anatomy and physiology, notwithstanding their extraordinary number and importance, could not be compared for merit and fruitfulness with the one discovery which furnished the key to so many riddles, he, no less than Darwin, by his influence on his successors was the beginner of a new era.

Müller taught in Berlin from 1833 to 1857. During that time a gradual change was in progress in the way in which biologists regarded the fundamental problem of life. Müller him-

[1] Bausner, *De Consensu Partium Humani Corporis*, Amst., 1556, Præf. ad lectorem, p. 4.

[2] These he identifies with "those complicated mutual relations which Darwin designates as conditions of the struggle for existence." Along with chorology—the distribution of animals—œcology constitutes what he calls *Relations-physiologie*. Haeckel, "Entwickelungsgang u. Aufgaben der Zoologie," *Jenaische Zeitschr.* vol. v. 1869, p. 353.

self, in common with Treviranus and all the biological teachers of his time, was a vitalist, *i.e.* he regarded what was then called the *vis vitalis*—the *Lebenskraft*—as something capable of being correlated with the physical forces; and as a necessary consequence held that phenomena should be classified or distinguished, according to the forces which produced them, as vital or physical, and that all those processes—that is groups or series of phenomena in living organisms—for which, in the then very imperfect knowledge which existed, no obvious physical explanation could be found, were sufficiently explained when they were stated to be dependent on so-called vital laws. But during the period of Müller's greatest activity times were changing, and he was changing with them. During his long career as professor at Berlin he became more and more objective in his tendencies, and exercised an influence in the same direction on the men of the next generation, teaching them that it was better and more useful to observe than to philosophise; so that, although he himself is truly regarded as the last of the vitalists—for he was a vitalist to the last—his successors were adherents of what has been very inadequately designated the mechanistic view of the phenomena of life. The change thus brought about just before the middle of this century was a revolution. It was not a substitution of one point of view for another, but simply a frank abandonment of theory for fact, of speculation for experiment. Physiologists ceased to theorise because they found something better to do. May I try to give you a sketch of this era of progress?

Great discoveries as to the structure of plants and animals had been made in the course of the previous decade, those especially which had resulted from the introduction of the microscope as an instrument of research. By its aid Schwann had been able to show that all organised structures are built up of those particles of living substance which we now call cells, and recognise as the seats and sources of every kind of vital activity. Hugo Mohl, working in another direction, had given the name "protoplasm" to a certain hyaline substance which forms the lining of the cells of plants, though no one as yet knew that it was the essential constituent of all living structures—the basis of life no less in animals than in plants. And, finally, a new branch of study—histology—founded on observations which the microscope had for the first time rendered possible, had come into existence. Bowman, one of the earliest and most successful cultivators of this new science, called it physiological anatomy,[1] and justified the title by the very important inferences as to the secreting function of epithelial cells and as to the nature of muscular contraction, which he deduced from his admirable anatomical researches. From structure to function, from microscopical observation to physiological experiment, the transition was natural. Anatomy was able to answer some questions, but asked many more. Fifty years ago physiologists had microscopes but had no laboratories. English physiologists—Bowman, Paget, Sharpey—were at the same time anatomists, and in Berlin Johannes Müller, along with anatomy and physiology, taught comparative anatomy and pathology. But soon that specialisation which, however much we may regret its necessity, is an essential concomitant of progress, became more and more inevitable. The structural conditions on which the processes of life depend, had become, if not known, at least accessible to investigation; but very little indeed had been ascertained of the nature of the processes themselves—so little indeed that if at this moment we could blot from the records of physiology the whole of the information which had been acquired, say in 1840, the loss would be difficult to trace—not that the previously known facts were of little value, but because every fact of moment has since been subjected to experimental verification. It is for this reason that, without any hesitation, we accord to Müller and to his successors Brücke, du Bois-Reymond, Helmholtz, who were his pupils, and Ludwig, in Germany, and to Claude Bernard[2] in France, the title of founders of our science. For it is the work which they began at that remarkable time (1845–55), and which is now being carried on by their pupils or their pupils' pupils in England, America, France, Germany, Denmark, Sweden, Italy, and even in that youngest contributor to the advancement of science, Japan, that physiology has been gradually built up to whatever completeness it has at present attained.

[1] The first part of the *Physiological Anatomy* appeared in 1843. It was concluded in 1856.

[2] It is worthy of note that these five distinguished men were merely contemporaries: Ludwig graduated in 1839, Bernard in 1843, the other three between those dates. Three survive—Helmholtz, Ludwig, du Bois-Reymond.

What were the conditions which brought about this great advance which coincided with the middle of the century? There is but little difficulty in answering the question. I have already said that the change was not one of doctrine, but of method. There was, however, a leading idea in the minds of those who were chiefly concerned in bringing it about. That leading notion was that, however complicated may be the conditions under which vital energies manifest themselves, they can be split into processes which are identical in nature with those of the non-living world, and, as a corollary to this, that the analysing of a vital process into its physical and chemical constituents, so as to bring these constituents into measurable relation with physical or chemical standards, is the only mode of investigating them which can lead to satisfactory results.

There were several circumstances which at that time tended to make the younger physiologists (and all of the men to whom I have just referred were then young) sanguine, perhaps too sanguine, in the hope that the application of experimental methods derived from the exact sciences would afford solutions of many physiological problems. One of these was the progress which had been made in the science of chemistry, and particularly the discovery that many of the compounds which before had been regarded as special products of vital processes could be produced in the laboratory, and the more complete knowledge which had been thereby acquired of their chemical constitutions and relations. In like manner, the new school profited by the advances which had been made in physics, partly by borrowing from the physical laboratory various improved methods of observing the phenomena of living beings, but chiefly in consequence of the direct bearing of the crowning discovery of that epoch (that of the conservation of energy) on the discussions which then took place as to the relations between vital and physical forces; in connection with which it may be noted that two of those who (along with Mr. Joule and your President at the last Nottingham meeting) took a prominent part in that discovery—Helmholtz and J. R. Mayer—were physiologists as much as they were physicists. I will not attempt even to enumerate the achievements of that epoch of progress. I may, however, without risk of wearying you, indicate the lines along which research at first proceeded, and draw your attention to the contrast between then and now. At present a young observer who is zealous to engage in research finds himself provided with the most elaborate means of investigation, the chief obstacle to his success being that the problems which have been left over by his predecessors are of extreme difficulty, all of the easier questions having been worked out. There were then also difficulties, but of an entirely different kind. The work to be done was in itself easier, but the means for doing it were wanting, and every investigator had to depend on his own resources. Consequently the successful men were those who, in addition to scientific training, possessed the ingenuity to devise and the skill to carry out methods for themselves. The work by which du Bois-Reymond laid the foundation of animal electricity would not have been possible had not its author, besides being a trained physicist, known how to do as good work in a small room in the upper floor of the old University building at Berlin as any which is now done in his splendid laboratory. Had Ludwig not possessed mechanical aptitude, in addition to scientific knowledge, he would have been unable to devise the apparatus by which he measured and recorded the variations of arterial pressure (1848), and verified the principles which Young had laid down thirty years before as to the mechanics of the circulation. Nor, lastly, could Helmholtz, had he not been a great deal more than a mere physiologist, have made those measurements of the time-relations of muscular and nervous responses to stimulation, which not only afford a solid foundation for all that has been done since in the same direction, but has served as models of physiological experiment, and as evidence that perfect work was possible and was done by capable men, even when there were no physiological laboratories.

Each of these examples relates to work done within a year or two of the middle of the century.[1] If it were possible to enter

[1] The "Untersuchungen über thierische Electricität" appeared in 1848; Ludwig's researches on the circulation, which included the first description of the "kymograph" and served as the foundation of the "graphic method" in 1847; Helmholtz's research on the propagation in motor nerves in 1851.

more fully on the scientific history of the time, we should, I think, find the clearest evidence, first, that the foundation was laid in anatomical discoveries, in which it is gratifying to remember that English anatomists (Allen Thomson, Bowman, Goodsir, Sharpey) took considerable share; secondly, that progress was rendered possible by the rapid advances which, during the previous decade, had been made in physics and chemistry, and the participation of physiology in the general awakening of the scientific spirit which these discoveries produced. I venture, however, to think that, notwithstanding the operation of these two causes, or rather combinations of causes, the development of our science would have been delayed had it not been for the exceptional endowments of the four or five young experimenters whose names I have mentioned, each of whom was capable of becoming a master in his own branch, and of guiding the future progress of inquiry.

Just as the affinities of an organism can be best learned from its development, so the scope of a science may be most easily judged of by the tendencies which it exhibits in its origin. I wish now to complete the sketch I have endeavoured to give of the way in which physiology entered on the career it has since followed for the last half-century, by a few words as to the influence exercised on general physiological theory by the progress of research. We have seen that no real advance was made until it became possible to investigate the phenomena of life by methods which approached more or less closely to those of the physicist, in exactitude. The methods of investigation being physical or chemical, the organism itself naturally came to be considered as a complex of such processes, and nothing more. And in particular the idea of adaptation, which, as I have endeavoured to show, is not a consequence of organism, but its essence, was in great measure lost sight of. Not, I think, because it was any more possible than before to conceive of the organism otherwise than as a working together of parts for the good of the whole, but rather that, if I may so express it, the minds of men were so occupied with new facts that they had not time to elaborate theories. The old meaning of the term "adaptation" as the equivalent of "design" had been abandoned, and no new meaning had yet been given to it, and consequently the word "mechanism" came to be employed as the equivalent of "process," as if the constant concomitance or sequence of two events was in itself a sufficient reason for assuming a mechanical relation between them. As in daily life so also in science, the misuse of words leads to misconceptions. To assert that the link between *a* and *b* is mechanical, for no better reason than that *b* always follows *a*, is an error of statement, which is apt to lead the incautious reader or hearer to imagine that the relation between *a* and *b* is understood, when in fact its nature may be wholly unknown. Whether or not at the time which we are considering, some physiological writers showed a tendency to commit this error, I do not think that it found expression in any generally accepted theory of life. It may, however, be admitted that the rapid progress of experimental investigation led to too confident anticipations, and that to some enthusiastic minds it appeared as if we were approaching within measurable distance of the end of knowledge. Such a tendency is, I think, a natural result of every signal advance. In an eloquent Harveian oration, delivered last autumn by Dr. Bridges, it was indicated how, after Harvey's great discovery of the circulation, men were too apt to found upon it explanations of all phenomena whether of health or disease, to such an extent that the practice of medicine was even prejudicially affected by it. In respect of its scientific importance the epoch we are considering may well be compared with that of Harvey, and may have been followed by an undue preference of the new as compared with the old, but no more permanent unfavourable results have shown themselves. As regards the science of medicine we need only remember that it was during the years between 1845 and 1860 that Virchow made those researches by which he brought the processes of disease into immediate relation with the normal processes of cell-development and growth, and so, by making pathology a part of physiology, secured its subsequent progress and its influence on practical medicine. Similarly in physiology, the achievements of those years led on without any interruption or drawback to those of the following generation; while in general biology, the revolution in the mode of regarding the internal processes of the animal or plant organism which resulted from these achievements, prepared the way for the acceptance of the still greater revolution which the Darwinian epoch brought about in the views entertained by naturalists of the relations of plants and animals to each other and to their surroundings.

It has been said that every science of observation begins by going out botanising, by which, I suppose, is meant that collecting and recording observations is the first thing to be done in entering on a new field of inquiry. The remark would scarcely be true of physiology, even at the earliest stage of its development, for the most elementary of its facts could scarcely be picked up as one gathers flowers in a wood. Each of the processes which go to make up the complex of life requires separate investigation, and in each case the investigation must consist in first splitting up the process into its constituent phenomena, and then determining their relation to each other, to the process of which they form part, and to the conditions under which they manifest themselves. It will, I think, be found that even in the simplest inquiry into the nature of vital processes some such order as this is followed. Thus, for example, if muscular contraction be the subject on which we seek information, it is obvious that, in order to measure its duration, the mechanical work it accomplishes, the heat wasted in doing it, the electro-motive forces which it develops, and the changes of form associated with these phenomena, special modes of observation must be used for each of them, that each measurement must be in the first instance separately made, under special conditions, and by methods specially adapted to the required purpose. In the synthetic part of the inquiry the guidance of experiment must again be sought for the purpose of discriminating between apparent and real causes, and of determining the order in which the phenomena occur. Even the simplest experimental investigations of vital processes are beset with difficulties. For, in addition to the extreme complexity of the phenomena to be examined and the uncertainties which arise from the relative inconstancy of the conditions of all that goes on in the living organism, there is this additional drawback, that, whereas in the exact sciences experiment is guided by well-ascertained laws, here the only principle of universal application is that of adaptation, and that even this cannot, like a law of physics, be taken as a basis for deductions, but only as a summary expression of that relation between external exciting causes and the reactions to which they give rise, which, in accordance with Treviranus' definition, is the essential character of vital activity.

The Specific Energies of the Organism.

When in 1826 J. Müller was engaged in investigating the physiology of vision and hearing he introduced into the discussion a term "specific energy," the use of which by Helmholtz[1] in his physiological writings has rendered it familiar to all students. Both writers mean by the word energy, not the "capacity of doing work," but simply *activity*, using it in its old-fashioned meaning, that of the Greek word from which it is derived. With the qualification "specific," it serves, perhaps, better than any other expression to indicate the way in which adaptation manifests itself. In this more extended sense the "specific energy" of a part or organ—whether that part be a secreting cell, a motor cell of the brain or spinal cord, or one of the photogenous cells which produce the light of the glowworm, or the protoplasmic plate which generates the discharge of the torpedo—is simply the special action which it *normally* performs, its norma or rule of action being in each instance the *interest of the organism* as a whole of which it forms part, and the exciting cause some influence outside of the excited structure, technically called a stimulus. It thus stands for a characteristic of living structures which seems to be universal. The apparent exceptions are to be found in those bodily activities which, following Bichat, we call vegetative, because they go on, so to speak, as a matter of course; but the more closely we look into them the more does it appear that they form no exception to the general rule, that every link in the chain of living action, however uniform that action may be, is a response to an antecedent influence. Nor can it well be doubted that, as every living cell or tissue is called upon to act in the interest of the whole, the organism must be capable of influencing every part so as to regulate its action. For, although there are some instances in which the channels of this influence are as yet unknown, the tendency of recent investigations has been to diminish the number of such instances. In general there is no difficulty in determining both the nature of the central influence exercised and the relation

1 "Handb. der physiologischen Optik," 1886, p. 233. Helmholtz uses the word in the plural—the "energies of the nerves of special sense."

between it and the normal function. It may help to illustrate this relation to refer to the expressive word *Auslösung* by which it has for many years been designated by German writers. This word stands for the performance of function by the "letting off" of "specific energies." Carrying out the notion of "letting off" as expressing the link between action and reaction, we might compare the whole process to the mode of working of a repeating clock (or other similar mechanism), in which case the pressure of the finger on the button would represent the external influence or stimulus, the striking of the clock, the normal reaction. And now may I ask you to consider in detail one or two illustrations of physiological reaction—of the *letting off of specific energy?*

The repeater may serve as a good example, inasmuch as it is, in biological language, a highly differentiated structure, to which a single function is assigned. So also in the living organism, we find the best examples of specific energy where Müller found them, namely, in the most differentiated, or, as we are apt to call them, the *highest* structures. The retina, with the part of the brain which belongs to it, together constitute such a structure, and will afford us therefore the illustration we want, with this advantage for our present purpose, that the phenomena are such as we all have it in our power to observe in ourselves. In the visual apparatus the principle of *normality* of reaction is fully exemplified. In the physical sense the word "light" stands for ether vibrations, but in the sensuous or subjective sense for sensations. The swings are the stimulus, the sensations are the reaction. Between the two comes the link, the "letting off," which it is our business to understand. Here let us remember that the man who first recognised this distinction between the physical and the physiological was not a biologist, but a physicist. It was Young who first made clear (though his doctrine fell on unappreciative ears) that, although in vision the external influences which give rise to the sensation of light are infinitely varied, the responses need not be more than three in number, each being, in Müller's language, a "specific energy" of some part of the visual apparatus. We speak of the organ of vision as *highly differentiated*, an expression which carries with it the suggestion of a distinction of rank between different vital processes. The suggestion is a true one; for it would be possible to arrange all those parts or organs of which the bodies of the *higher* animals consist in a series, placing at the lower end of the series those of which the functions are continuous, and therefore called vegetative; at the other, those highly specialised structures, as, *e.g.*, those in the brain, which in response to physical light produce physiological, that is subjective, light; or, to take another instance, the so-called motor cells of the surface of the brain, which in response to a stimulus of much greater complexity produce voluntary motion. And just as in civilised society an individual is valued according to his power of doing one thing well, so the high rank which is assigned to the structure, or rather to the "specific energy" which it represents, belongs to it by virtue of its specialisation. And if it be asked how this conformity is manifested, the answer is, by the quality, intensity, duration, and extension of the response, in all which respects vision serves as so good an example, that we can readily understand how it happened that it was in this field that the relation between response and stimulus was first clearly recognised. I need scarcely say that, however interesting it might be to follow out the lines of inquiry thus indicated, we cannot attempt it this evening. All that I can do is to mention one or two recent observations which, while they serve as illustrations, may perhaps be sufficiently novel to interest even those who are at home in the subject.

Probably every one is acquainted with some of the familiar proofs that an object is seen for a much longer period than it is actually exposed to view; that the visual reaction lasts much longer than its cause. More precise observations teach us that this response is regulated according to laws which it has in common with all the higher functions of an organism. If, for example, the cells in the brain of the torpedo are "let off"—that is, awakened by an external stimulus—the electrical discharge, which, as in the case of vision, follows after a certain interval, lasts a certain time, first rapidly increasing to a maximum of intensity, then more slowly diminishing. In like manner, as regards the visual apparatus, we have, in the response to a sudden invasion of the eye by light, a rise and fall of a similar character. In the case of the electrical organ, and in many analogous instances, it is easy to investigate the time relations of the successive phenomena, so as to represent them graphically. Again, it is found that in many physiological reactions, the period of rising "energy" (as Helmholtz called it), is followed by a period during which the responding structure is not only inactive, but its capacity for energising is so completely lost that the same exciting cause which a moment before "let off" the characteristic response is now without effect. As regards vision, it has long been believed that these general characteristics of physiological reaction have their counterpart in the visual process, the most striking evidence being that in the contemplation of a lightning flash—or better, of an instantaneously illuminated white disc[1]—the eye seems to receive a double stroke, indicating that, although the stimulus is single and instantaneous, the response is reduplicated. The most precise of the methods we until lately possessed for investigating the wax and wane of the visual reaction, were not only difficult to carry out but left a large margin of uncertainty. It was therefore particularly satisfactory when M. Charpentier, of Nancy, whose merits as an investigator are perhaps less known than they deserve to be, devised an experiment of extreme simplicity which enables us, not only to observe, but to measure with great facility both phases of the reaction. It is difficult to explain even the simplest apparatus without diagrams; you will, however, understand the experiment if you will imagine that you are contemplating a disc, like those ordinarily used for colour mixing; that it is divided by two radial lines which diverge from each other at an angle of 60°; that the sector which these lines enclose is white, the rest black; that the disc revolves slowly, about once in two seconds. You then see, close to the front edge of the advancing sector, a black bar, followed by a second at the same distance from itself but much fainter. Now the scientific value of the experiment consists in this, that the angular distance of the bar from the black border is in proportion to the frequency of the revolutions—the faster the wider. If, for example, when the disc makes half a revolution in a second the distance is ten degrees, this obviously means that when light bursts into the eye, the extinction happens one-eighteenth of a second after the excitation.[2]

The fact thus demonstrated, that the visual reaction consequent on an instantaneous illumination exhibits the alternations I have described, has enabled M. Charpentier to make out another fact in relation to the visual reaction which is, I think, of equal importance. In all the instances, excepting the retina, in which the physiological response to stimulus has a definite time-limitation, and in so far resembles an explosion—in other words, in all the higher forms of specific energy, it can be shown experimentally that the process is propagated from the part first directly acted on to other contiguous parts of similar endowment. Thus in the simplest of all known phenomena of this kind, the electrical change, by which the leaf of the Dionæa plant responds to the slightest touch of its sensitive hairs, is propagated from one side of the leaf to the other, so that in the opposite lobe the response occurs after a delay which is proportional to the distance between the spot excited and the spot observed. That in the retina there is also such propagation has not only been surmised from analogy, but inferred from certain observed facts. M. Charpentier has now been able by a method which, although simple, I must not attempt to describe, not only to prove its existence, but to measure its rate of progress over the visual field.

There is another aspect of the visual response to the stimulus of light which, if I am not trespassing too long on your patience, may, I think, be interesting to consider. As the relations between the sensations of colour and the physical properties of the light which excites them, are among the most certain and invariable in the whole range of vital reactions, it is obvious that they afford as fruitful a field for physiological investigation as those in which white light is concerned. We have on one side physical facts, that is, wave-lengths or vibration-rates; on the other, facts in consciousness—namely, sensations of colour—so simple that notwithstanding their subjective character there is no difficulty in measuring either their intensity or their duration. Between these there are *lines of influence*, neither physical nor psychological, which pass from the former to the latter through the visual apparatus (retina, nerve, brain).

1 The phenomenon is best seen when, in a dark room, the light of a luminous spark is thrown on to a white screen with the aid of a suitable lens.

2 Charpentier, "Réaction oscillatoire de la Rétine sous l'influence des excitations lumineuses," *Archives de Physiol.*, vol. xxiv. p. 541, and *Propagation de l'action oscillatoire*, &c., p. 362.

It is these lines of influence which interest the physiologist. The structure of the visual apparatus affords us no clues to trace them by. The most important fact we know about them is that they must be at least three in number.

It has been lately assumed by some that vision, like every other specific energy, having been developed progressively, objects were seen by the most elementary forms of eye only in chiaroscuro, that afterwards some colours were distinguished, eventually all. As regards hearing it is so. The organ which, on structural grounds, we consider to represent that of hearing in animals low in the scale of organisation—as, *e.g.*, in the Ctenophora—has nothing to do with sound,[1] but confers on its possessor the power of judging of the direction of its own movements in the water in which it swims, and of guiding these movements accordingly. In the lowest vertebrates, as, *e.g.*, in the dogfish, although the auditory apparatus is much more complicated in structure, and plainly corresponds with our own, we still find the particular part which is concerned in hearing scarcely traceable. All that is provided for is that sixth sense, which the higher animals also possess, and which enables them to judge of the direction of their own movements. But a stage higher in the vertebrate series we find the special mechanisms by which we ourselves appreciate sounds beginning to appear—not supplanting or taking the place of the imperfect organ, but added to it. As regards hearing, therefore, a new function is acquired without any transformation or fusion of the old into it. We ourselves possess the sixth sense, by which we keep our balance and which serves as the guide to our bodily movements. It resides in the part of the internal ear which is called the labyrinth. At the same time we enjoy along with it the possession of the cochlea, that more complicated apparatus by which we are able to hear sounds and to discriminate their vibration-rates.

As regards vision, evidence of this kind is wanting. There is, so far as I know, no proof that visual organs which are so imperfect as to be incapable of distinguishing the forms of objects, may not be affected differently by their colours. Even if it could be shown that the least perfect forms of eye possess only the power of discriminating between light and darkness, the question whether in our own such a faculty exists separately from that of distinguishing colours is one which can only be settled by experiment. As in all sensations of colour the sensation of brightness is mixed, it is obvious that one of the first points to be determined is whether the latter represents a "specific energy" or merely a certain combination of specific energies which are excited by colours. The question is not whether there is such a thing as white light, but whether we possess a separate faculty by which we judge of light and shade—a question which, although we have derived our knowledge of it chiefly from physical experiment, is one of eye and brain, not of wave-lengths or vibration-rates, and is therefore essentially physiological.

There is a German proverb which says, "Bei Nacht sind alle Katzen grau." The fact which this proverb expresses presents itself experimentally when a spectrum projected on a white surface is watched, while the intensity of the light is gradually diminished. As the colours fade away they become indistinguishable as such, the last seen being the primary red and green. Finally they also disappear, but a gray band of light still remains, of which the most luminous part is that which before was green.[2] Without entering into details, let us consider what this tells us of the specific energy of the visual apparatus. Whether or not the faculty by which we see gray in the dark is one which we possess in common with animals of imperfectly developed vision, there seems little doubt that there are individuals of our own species who, in the fullest sense of the expression, have no eye for colour; in whom all colour sense is absent; persons who inhabit a world of gray, seeing all things as they might have done had they and their ancestors always lived nocturnal lives. In the theory of colour vision, as it is commonly stated, no reference is made to such a faculty as we are now discussing.

Prof. Hering, whose observations as to the diminished spectrum I referred to just now, who was among the first to subject the vision of the *totally* colour-blind to accurate examination, is of opinion, on that and on other grounds, that the sensation of light and shade is a specific faculty. Very recently the same view has been advocated on a wide basis by a distinguished psychologist, Prof. Ebbinghaus.[1] Happily, as regards the actual experimental results relating to both these main subjects, there seems to be a complete coincidence of observation between observers who interpret them differently. Thus the recent elaborate investigations of Captain Abney[2] (with General Festing), representing graphically the results of his measurements of the subjective values of the different parts of the diminished spectrum, as well as those of the fully illuminated spectrum as seen by the totally colour-blind, are in the closest accord with the observations of Hering, and have, moreover, been substantially confirmed in both points by the measurements of Dr. König in Helmholtz' laboratory at Berlin.[3] That observers of such eminence as the three persons whom I have mentioned, employing different methods and with a different purpose in view, and without reference to each other's work, should arrive in so complicated an inquiry at coincident results, augurs well for the speedy settlement of this long-debated question. At present the inference seems to be that such a specific energy as Hering's theory of vision postulates actually exists, and that it has for associates the colour-perceiving activities of the visual apparatus, provided that these are present; but that whenever the intensity of the illumination is below the chromatic threshold—that is, too feeble to awaken these activities—or when, as in the totally colour-blind, they are wanting, it manifests itself independently; all of which can be most easily understood on such a hypothesis as has lately been suggested in an ingenious paper by Mrs. Ladd Franklin,[4] that each of the elements of the visual apparatus is made up of a central structure for the sensation of light and darkness, with collateral appendages for the sensations of colour—it being, of course, understood that this is a mere diagrammatic representation, which serves no purposes beyond that of facilitating the conception of the relation between the several "specific energies."

Experimental Psychology.

Resisting the temptation to pursue this subject further, I will now ask you to follow me into a region which, although closely connected with the subjects we have been considering, is beset with greater difficulties—the subject in which, under the name of Physiological or Experimental Psychology, physiologists and psychologists have of late years taken a common interest—a borderland not between fact and fancy, but between two methods of investigation of questions which are closely related, which here, though they do not overlap, at least interdigitate. It is manifest that, quite irrespectively of any foregone conclusion as to the dependence of mind on processes of which the biologist is accustomed to take cognisance, mind must be regarded as one of the "specific energies" of the organism, and should on that ground be included in the subject-matter of physiology. As, however, our science, like other sciences, is limited not merely by its subject but also by its method, it actually takes in only so much of psychology as is experimental. Thus sensation, although it is psychological, and the investigation of its relation to the special structures by which the mind keeps itself informed of what goes on in the outside world, have always been considered to be in the physiological sphere. And it is by anatomical researches relating to the minute structure and to the development of the brain, by observation of the facts of disease, and, above all, by physiological experiment, that those changes in the ganglion cells of the brain and spinal cord which are the immediate antecedents of every kind of bodily action have been traced. Between the two—that is, between sensation and the beginning of action—there is an intervening region which the physiologist has hitherto willingly resigned to psychology, feeling his incompetence to use the only instrument by which it can be explored—that of introspection. This consideration enables us to understand the course which the new study (I will not claim for it the title of a new science, regard-

ing it as merely a part of the great science of life) has hitherto followed, and why physiologists have been unwilling to enter on it. The study of the less complicated internal relations of the organism has afforded so many difficult problems that the most difficult of all have been deferred; so that although the psycho-physical method was initiated by E. H. Weber in the middle of the present century, by investigations [1] which formed part of the work done at that epoch of discovery, and although Prof. Wundt, also a physiologist, has taken a larger share in the more recent development of the new study, it is chiefly by psychologists that the researches which have given to it its importance as a new discipline have been conducted.

Although, therefore, experimental psychology has derived its methods from physical science, the result has been not so much that physiologists have become philosophers, as that philosophers have become experimental psychologists. In our own universities, in those of America, and still more in those of Germany, psychological students of mature age are to be found who are willing to place themselves in the dissecting-room side by side with beginners in anatomy, in order to acquire that exact knowledge of the framework of the organism without which no man can understand its working. Those, therefore, who are apprehensive lest the regions of mind should be invaded by the *insaniens sapientia* of the laboratory, may, I think, console themselves with the thought that the invaders are for the most part men who before they became laboratory workers had already given their allegiance to philosophy; their purpose being not to relinquish definitively, but merely to lay aside for a time, the weapons in the use of which they had been trained, in order to learn the use of ours. The motive that has encouraged them has not been any hope of finding an experimental solution of any of the ultimate problems of philosophy, but the conviction that, inasmuch as the relation between mental stimuli and the mental processes which they awaken is of the same order with the relation between every other vital process and its specific determinant, the only hope of ascertaining its nature must lie in the employment of the same methods of comparative measurement which the biologist uses for similar purposes. Not that there is necessarily anything scientific in mere measurement, but that measurement affords the only means by which it can be determined whether or not the same conformity in the relation between stimulus and reaction which we have accepted as the fundamental characteristic of life, is also to be found in mind, notwithstanding that mental processes have no known physical concomitants. The results of experimental psychology tend to show that it is so, and consequently that in so far the processes in question are as truly functions of organism as the contraction of a muscle, or as the changes produced in the retinal pigment by light.

I will make no attempt even to enumerate the special lines of inquiry which during the last decade have been conducted with such vigour in all parts of the world, all of them traceable to the influence of the Leipzig school; but will content myself with saying that the general purpose of these investigations has been to determine with the utmost attainable precision the nature of psychical relations. Some of these investigations begin with those simpler reactions which more or less resemble those of an automatic mechanism, proceeding to those in which the resulting action or movement is modified by the influence of auxiliary or antagonistic conditions, or changed by the simultaneous or antecedent action on the reagent of other stimuli, in all of which cases the effect can be expressed quantitatively; others lead to results which do not so readily admit of measurement. In pursuing this course of inquiry the physiologist finds himself as he proceeds more and more the *coadjutor* of the psychologist, less and less his *director*; for whatever advantage the former may have in the mere *technique* of observation, the things with which he has to do are revealed only to introspection, and can be studied only by methods which lie outside of his sphere. I might in illustration of this refer to many recent experimental researches—such, for example, as those by which it has been sought to obtain exact data as to the physiological concomitants of pleasure and of pain, or as to the influence of weariness and recuperation, as modifiers of psychological reactions. Another outwork of the mental citadel which has been invaded by the experimental method is that of memory. Even here it can be shown that in the comparison of transitory as compared with permanent memory—as, for example, in the getting off by heart of a wholly uninteresting series of words, with subsequent oblivion and reacquisition—the labour of acquiring and reacquiring may be measured, and consequently the relation between them; and that this ratio varies according to a simple numerical law.

[1] Weber's researches were published in Wagner's *Handwörterbuch*, I think, in 1849.

I think it not unlikely that the only effect of what I have said may be to suggest to some of my hearers the question, What is the use of such inquiries? Experimental psychology has, to the best of my knowledge, no technical application. The only satisfactory answer I can give is that it has exercised, and will exercise in future, a helpful influence on the science of life. Every science of observation, and each branch of it, derives from the peculiarities of its methods certain tendencies which are apt to predominate unduly. We speak of this as specialisation, and are constantly striving to resist its influence. The most successful way of doing so is by availing ourselves of the counteracting influence which two opposite tendencies mutually exercise when they are simultaneous. He that is skilled in the methods of introspection naturally (if I may be permitted to say so) looks at the same thing from an opposite point of view to that of the experimentalist. It is, therefore, good that the two should so work together that the tendency of the experimentalist to imagine the existence of mechanism where none is proved to exist—of the psychologist to approach the phenomena of mind too exclusively from the subjective side—may mutually correct and assist each other.

Phototaxis and Chemiotaxis.

Considering that every organism must have sprung from a unicellular ancestor, some have thought that unless we are prepared to admit a deferred epigenesis of mind, we must look for psychical manifestations even among the lowest animals, and that as in the protozoon all the vital activities are blended together, mind should be present among them not merely potentially but actually, though in diminished degree.

Such a hypothesis involves ultimate questions which it is unnecessary to enter upon: it will, however, be of interest in connection with our present subject to discuss the phenomena which served as a basis for it—those which relate to what may be termed the behaviour of unicellular organisms and of individual cells, in so far as these last are capable of reacting to external influences. The observations which afford us most information are those in which the stimuli employed can be easily measured, such as electrical currents, light, or chemical agents in solution.

A single instance, or at most two, must suffice to illustrate the influence of light in directing the movements of freely moving cells, or, as it is termed, phototaxis. The rod-like purple organism called by Engelmann *Bacterium photometricum*,[1] is such a light-lover that if you place a drop of water containing these organisms under the microscope, and focus the smallest possible beam of light on a particular spot in the field, the spot acts as a light trap and becomes so crowded with the little rodlets as to acquire a deep port-wine colour. If instead of making his trap of white light, he projected on the field a microscopic spectrum, Engelmann found that the rodlets showed their preference for a spectral colour, which is absorbed when transmitted through their bodies. By the aid of a light trap of the same kind, the very well-known spindle-shaped and flagellate cell of Euglena can be shown to have a similar power of discriminating colour, but its preference is different. This familiar organism advances with its flagellum forwards, the sharp end of the spindle having a red or orange eye point. Accordingly, the light it loves is again that which is most absorbed—viz., the blue of the spectrum (line F).

These examples may serve as an introduction to a similar one in which the directing cause of movement is not physical but chemical. The spectral light trap is used in the way already described; the organisms to be observed are not coloured, but bacteria of that common sort which twenty years ago we used to call *Bacterium termo*, and which is recognised as the ordinary determining cause of putrefaction. These organisms do not care for life, but are great oxygen-lovers. Consequently, if you illuminate with your spectrum a filament of a confervoid alga, placed in water containing bacteria, the assimilation of carbon and consequent disengagement of oxygen is most active in the part of the filament which receives the red rays (B to C). To

[1] Engelmann, "Bacterium photometricum," *Onderzoek. Physiol Lab. Utrecht*, vol. vii. p. 200; also Ueber Licht-u. Farbenperception niederster Organismen, *Pflüger's Arch*, vol. xxix. p. 387.

this part, therefore, where there is a dark band of absorption, the bacteria which want oxygen are attracted in crowds. The motive which brings them together is their desire for oxygen. Let us compare other instances in which the source of attraction is food.

The plasmodia of the myxomycetes, particularly one which has been recently investigated by Mr. Arthur Lister,[1] may be taken as a typical instance of what may be called the chemical allurement of living protoplasm. In this organism, which in the active state is an expansion of labile living material, the delicacy of the reaction is comparable to that of the sense of smell in those animals in which the olfactory organs are adapted to an aquatic life. Just as, for example, the dogfish is attracted by food which it cannot see, so the plasmodium of Badhamia becomes aware, as if it smelled it, of the presence of its food—a particular kind of fungus. I have no diagram to explain this, but will ask you to imagine an expansion of living material, quite structureless, spreading itself along a wet surface; that this expansion of transparent material is bounded by an irregular coast-line; and that somewhere near the coast there has been placed a fragment of the material on which the Badhamia feeds. The presence of this bit of *Stereum* produces an excitement at the part of the plasmodium next to it. Towards this centre of activity streams of living material converge. Soon the afflux leads to an outgrowth of the plasmodium, which in a few minutes advances towards the desired fragment, envelopes, and incorporates it.

May I give you another example also derived from the physiology of plants? Very shortly after the publication of Engelmann's observations of the attraction of bacteria by oxygen, Pfeffer made the remarkable discovery that the movements of the antherozoids of ferns and of mosses are guided by impressions derived from chemical sources, by the allurement exercised upon them by certain chemical substances in solution—in one of the instances mentioned by sugar, in the other by an organic acid. The method consisted in introducing the substance to be tested, in any required strength, into a minute capillary tube closed at one end, and placing it under the microscope in water inhabited by antherozoids, which thereupon showed their predilection for the substance, or the contrary, by its effect on their movements. In accordance with the principle followed in experimental psychology, Pfeffer[2] made it his object to determine, not the relative effects of different doses, but the smallest perceptible increase of dose which the organism was able to detect, with this result—that, just as in measurements of the relation between stimulus and reaction in ourselves we find that the sensational value of a stimulus depends, not on its absolute intensity, but on the ratio between that intensity and the previous excitation, so in this simplest of vital reagents the same so-called psycho-physical law manifests itself. It is not, however, with a view to this interesting relation that I have referred to Pfeffer's discovery, but because it serves as a centre around which other phenomena, observed alike in plants and animals, have been grouped. As a general designation of reactions of this kind Pfeffer devised the term Chemotaxis, or, as we in England prefer to call it, Chemiotaxis. Pfeffer's contrivance for chemiotactic testing was borrowed from the pathologists, who have long used it for the purpose of determining the relation between a great variety of chemical compounds or products, and the colourless corpuscles of the blood. I need, I am sure, make no apology for referring to a question which, although purely pathological, is of very great biological interest—the theory of the process by which, not only in man, but also, as Metschnikoff has strikingly shown, in animals far down in the scale of development, the organism protects itself against such harmful things as, whether particulate or not, are able to penetrate its framework. Since Cohnheim's great discovery in 1867 we have known that the central phenomenon of what is termed by pathologists *inflammation* is what would now be called a chemiotactic one; for it consists in the gathering together, like that of vultures to a carcase, of those migratory cells which have their home in the blood stream and in the lymphatic system, to any point where the living tissue of the body has been injured or damaged, as if the products of disintegration which are set free where such damage occurs were attractive to them.

The fact of chemiotaxis, therefore, as a constituent phenomenon of the process of inflammation, was familiar in pathology long before it was understood. Cohnheim himself attributed it to changes in the channels along which the cells moved, and this explanation was generally accepted, though some writers, at all events, recognised its incompleteness. But no sooner was Pfeffer's discovery known than Leber,[1] who for years had been working at the subject from the pathological side, at once saw that the two processes were of similar nature. Then followed a variety of researches of great interest, by which the importance of chemiotaxis in relation to the destruction of disease-producing microphytes was proved, by that of Buchner[2] on the chemical excitability of leucocytes being among the most important. Much discussion has taken place, as many present are aware, as to the kind of wandering cells, or leucocytes, which in the first instance attack morbific microbes, and how they deal with them. The question is not by any means decided. It has, however, I venture to think, been conclusively shown that the process of destruction is a chemical one, that the destructive agent has its source in the chemiotactic cells—that is, cells which act under the orders of chemical stimuli. Two Cambridge observers, Messrs. Kanthack and Hardy,[3] have lately shown that, in the particular instance which they have investigated, the cells which are most directly concerned in the destruction of morbific *bacilli*, although chemiotactic, do not possess the power of incorporating bacilli or particles of any other kind. While, therefore, we must regard the relation between the process of devitalising and that of incorporating as not yet sufficiently determined, it is now no longer possible to regard the latter as essential to the former.

There seems, therefore, to be very little doubt that chemiotactic cells are among the agents by which the human or animal organism protects itself against infection. There are, however, many questions connected with this action which have not yet been answered. The first of these are chemical ones—that of the nature of the attractive substance and that of the process by which the living carriers of infection are destroyed. Another point to be determined is how far the process admits of adaptation to the particular infection which is present in each case, and to the state of liability or immunity of the infected individual. The subject is therefore of great complication. None of the points I have suggested can be settled by experiments in glass tubes such as I have described to you. These serve only as indications of the course to be followed in much more complicated and difficult investigations—when we have to do with acute diseases as they actually affect ourselves or animals of similar liability to ourselves, and find ourselves face to face with the question of their causes.

It is possible that many members of the Association are not aware of the unfavourable—I will not say discreditable—position that this country at present occupies in relation to the scientific study of this great subject—the causes and mode of prevention of infectious diseases. As regards administrative efficiency in matters relating to public health England was at one time far ahead of all other countries, and still retains its superiority; but as regards scientific knowledge we are, in this subject as in others, content to borrow from our neighbours. Those who desire either to learn the methods of research or to carry out scientific inquiries, have to go to Berlin, to Munich, to Breslau, or to the Pasteur Institute in Paris, to obtain what England ought long ago to have provided. For to us, from the spread of our race all over the world, the prevention of acute infectious diseases is more important than to any other nation. At the beginning of this address I urged the claims of pure science. If I could, I should feel inclined to speak even more strongly of the application of science to the discovery of the causes of acute diseases. May I express the hope that the effort which is now being made to establish in England an institution for this purpose not inferior in efficiency to those of other countries, may have the sympathy of all present? And now may I ask your attention for a few moments more to the subject that more immediately concerns us?

Conclusion.

The purpose which I have had in view has been to show that there is one principle—that of adaptation—which separates

biology from the exact sciences, and that in the vast field of biological inquiry the end we have is not merely, as in natural philosophy, to investigate the relation between the phenomenon and the antecedent and concomitant conditions on which it depends, but to possess this knowledge in constant reference to the interest of the organism. It may perhaps be thought that this way of putting it is too teleological, and that in taking, as it were, as my text this evening so old-fashioned a biologist as Treviranus, I am yielding to a retrogressive tendency. It is not so. What I have desired to insist on is that *organism* is a fact which encounters the biologist at every step in his investigations; that in referring it to any general biological principle, such as adaptation, we are only referring it to itself, not explaining it; that no explanation will be attainable until the conditions of its coming into existence can be subjected to experimental investigation so as to correlate them with those of processes in the non-living world.

Those who were present at the meeting of the British Association at Liverpool, will remember that then, as well as at some subsequent meetings, the question whether the conditions necessary for such an inquiry could be realised was a burning one. This is no longer the case. The patient endeavours which were made about that time to obtain experimental proof of what was called *abiogenesis*, although they conduced materially to that better knowledge which we now possess of the conditions of life of bacteria, failed in the accomplishment of their purpose. The question still remains undetermined; it has, so to speak, been adjourned *sine die*. The only approach to it lies at present in the investigation of those rare instances in which, although the relations between a living organism and its environment ceases as a watch stops when it has not been wound, these relations can be re-established—the process of life reawakened—by the application of the required stimulus.

I was also desirous to illustrate the relation between physiology and its two neighbours on either side, natural philosophy (including chemistry) and psychology. As regards the latter, I need add nothing to what has already been said. As regards the former, it may be well to notice that although physiology can never become a mere branch of applied physics or chemistry, there are parts of physiology wherein the principles of these sciences may be applied directly. Thus, in the beginning of the century, Young applied his investigations as to the movements of liquids in a system of elastic tubes, directly to the phenomena of the circulation; and a century before, Borelli successfully examined the mechanisms of locomotion and the action of muscles, without reference to any, excepting mechanical principles. Similarly, the foundation of our present knowledge of the process of nutrition was laid in the researches of Bidder and Schmidt, in 1851, by determinations of the weight and composition of the body, the daily gain of weight by food or oxygen, the daily loss by the respiratory and other discharges, all of which could be accomplished by chemical means. But in by far the greater number of physiological investigations, both methods (the physical or chemical and the physiological) must be brought to bear on the same question—to co-operate for the elucidation of the same problem. In the researches, for example, which during several years have occupied Prof. Bohr, of Copenhagen, relating to the exchange of gases in respiration, he has shown that factors purely physical—namely, the partial pressures of oxygen and carbon dioxide in the blood which flows through the pulmonary capillaries—are, so to speak, interfered with in their action by the "specific energy" of the pulmonary tissue, in such a way as to render this fundamental process, which, since Lavoisier, has justly been regarded as one of the most important in physiology, much more complicated than we for a long time supposed it to be. In like manner Heidenhain has proved that the process of lymphatic absorption, which before we regarded as dependent on purely mechanical causes—*i.e.* differences of pressure—is in great measure due to the specific energy of cells, and that in various processes of secretion the principal part is not, as we were inclined not many years ago to believe, attributable to liquid diffusion, but to the same agency. I wish that there had been time to have told you something of the discoveries which have been made in this particular field by Mr. Langley, who has made the subject of "specific energy" of secreting-cells his own. It is in investigations of this kind, of which any number of examples could be given, in which vital reactions mix themselves up with physical and chemical ones so intimately that it is difficult to draw the line between them, that the physiologist derives most aid from whatever chemical and physical training he may be fortunate enough to possess.

There is, therefore, no doubt as to the advantages which physiology derives from the exact sciences. It could scarcely be averred that they would benefit in anything like the same degree from closer association with the science of life. Nevertheless, there are some points in respect of which that science may have usefully contributed to the advancement of physics or of chemistry. The discovery of Graham as to the characters of colloid substances, and as to the diffusion of bodies in solution through membranes, would never have been made had not Graham "ploughed," so to speak, "with our heifer." The relations of certain colouring matters to oxygen and carbon dioxide would have been unknown, had no experiments been made on the respiration of animals and the assimilative process in plants; and, similarly, the vast amount of knowledge which relates to the chemical action of ferments must be claimed as of physiological origin. So also there are methods, both physical and chemical, which were originally devised for physiological purposes. Thus the method by which meteorological phenomena are continuously recorded graphically, originated from that used by Ludwig (1847) in his "Researches on the Circulation"; the mercurial pump, invented by Lothar Meyer, was perfected in the physiological laboratories of Bonn and Leipzig; the rendering the galvanometer needle aperiodic by damping was first realised by du Bois-Reymond—in all of which cases invention was prompted by the requirements of physiological research.

Let me conclude with one more instance of a different kind, which may serve to show how, perhaps, the wonderful ingenuity of contrivance which is displayed in certain organised structures—the eye, the ear, or the organ of voice—may be of no less interest to the physicist than to the physiologist. Johannes Müller, as is well known, explained the compound eye of insects on the theory that an erect picture is formed on the convex retina by the combination of pencils of light, received from different parts of the visual field through the eyelets (ommatidia) directed to them. Years afterwards it was shown that in each eyelet an image is formed which is reversed. Consequently, the mosaic theory of Müller was for a long period discredited on the ground that an erect picture could not be made up of "upside-down" images. Lately the subject has been reinvestigated, with the result that the mosaic theory has regained its authority. Prof. Exner[1] has proved photographically that behind each part of the insect's eye an erect picture is formed of the objects towards which it is directed. There is, therefore, no longer any difficulty in understanding how the whole field of vision is mapped out as consistently as it is imaged on our own retina, with the difference, of course, that the picture is erect. But behind this fact lies a physical question—that of the relation between the erect picture which is photographed and the optical structure of the crystal cones which produce it—a question which, although we cannot now enter upon it, is quite as interesting as the physiological one.

With this history of a theory which, after having been for thirty years disbelieved, has been reinstated by the fortunate combination of methods derived from the two sciences, I will conclude. It may serve to show how, though physiology can never become a part of natural philosophy, the questions we have to deal with are cognate. Without forgetting that every phenomenon has to be regarded with reference to its useful purpose in the organism, the aim of the physiologist is not to inquire into final causes, but to investigate processes. His question is ever How, rather than Why.

May I illustrate this by a simple, perhaps too trivial, story, which derives its interest from its having been told of the childhood of one of the greatest natural philosophers of the present century?[2] He was even then possessed by that insatiable curiosity which is the first quality of the investigator; and it is related of him that his habitual question was "What is the *go* of it?" and if the answer was unsatisfactory, "What is the particular go of it?" That North Country boy became Prof. Clerk Maxwell. The questions he asked are those which in our various ways we are all trying to answer.

SECTION A.

MATHEMATICS AND PHYSICS.

OPENING ADDRESS BY R. T. GLAZEBROOK, M.A., F.R.S., PRESIDENT OF THE SECTION.

BEFORE dealing with the subject which I hope to bring to your notice this morning, I wish to express my deep regret for the circumstances which have prevented Prof. Clifton, who had accepted the nomination of the Council, from being your President this year.

It was specially fitting that he who has done so much for this college, and particularly for this laboratory in which we meet, should take the chair at Nottingham. The occasions on which we see him are all too seldom; and we who come frequently to these meetings were looking forward to help and encouragement in our work, derived from his wide experience. You would desire, I feel sure, that I should convey to him the expressions of your sympathy. For myself I must ask that you will pass a lenient judgment on my efforts to fill his place.

Let me commence, then, with a brief retrospect of the past year and the events which concern our Section.

From the days of Galileo the four satellites of Jupiter have been objects of interest to the astronomer. Their existence was one of the earliest of the discoveries of the telescope; they proved conclusively that all the bodies of the solar system did not move round the earth. The year which has passed since our last meeting is memorable for the discovery of a fifth satellite. It is a year to day (September 13–14, 1892) since Prof. Barnard convinced himself that he had seen with the great telescope of the Lick Observatory this new member of our system as a star of the thirteenth magnitude, revolving round the planet in 11 hours 57 minutes 23 seconds.[1]

The conference on electrical standards, held at our meeting last year, has had important results. The resolutions adopted at Edinburgh were communicated to the Standards Committee of the Board of Trade. A supplementary report accepting these resolutions was agreed to by that Committee (November 29, 1892), and presented to the President of the Board of Trade. The definitions contained in this report will be made the basis of legislation throughout the world. They have been accepted by France, Germany, Austria, and Italy. The congress at Chicago, which has just been held, has ratified them, and thus we may claim that your Committee, co-operating with the leaders of physical science in other lands, has secured international agreement on these fundamental points.

Among the physical papers of the year I would mention a few as specially calling for notice. Mr. E. H. Griffiths's redetermination of the value of the mechanical equivalent of heat has just been published (*Phil. Trans.* vol. clxxxiv.), and is a monumental work. With untiring energy and great ability he struggled for five years against the difficulties of his task, and has produced results which, with the exception of one group of experiments, do not differ by more than 1 part in 10,000; while the results of that one excepted group differ from the mean only by 1 part in 4000.

The number of ergs of work required to raise one gramme of water 1° C. at 15° C. is $4{\cdot}198 \times 10^7$. Expressed in foot-pounds and Fahrenheit degrees, the value of J is 779·97. The value obtained by Joule from his experiments on the friction of water, when corrected in 1880 by Rowland so as to reduce his readings to the air thermometer, is 778·5 at 12°·7 C. The result at this temperature of Rowland's own valuable research is 780·1. Another satisfactory outcome of Mr. Griffiths's work is the very exact accordance between the scale of temperature as determined by the comparison of his platinum thermometer with the air thermometer, which was made by Callendar and himself in 1890, and that of the nitrogen thermometer of the Bureau International at Sèvres.

Another great work now happily complete is Rowland's "Table of Standard Wave-lengths" (*Phil. Mag.*, July, 1893). Nearly a thousand lines have been measured with the skill and accuracy for which Rowland has made himself famous; and in this table we see the results achieved by the genius which designed the concave grating and the mechanical ingenuity which contrived the almost perfect screw.

Those of us who have seen Mr. Higgs's wonderful photographs of the solar spectrum, taken with a Rowland grating, will rejoice to know that his map also is now finished.

Lord Rayleigh's paper on "The Intensity of Light reflected from Water and Mercury at nearly perpendicular incidence," (*Phil. Mag.*, October, 1892), combined with the experiments on reflexion from liquid surfaces in the neighbourhood of the polarising angle (*Phil. Mag.*, January, 1892), establishes results of the utmost importance to optical theory. "There is thus," Lord Rayleigh concludes, "no experimental evidence against the rigorous application of Fresnel's formulæ"—for the reflexion of polarised light—"to the ideal case of an abrupt transition between two uniform transparent media."

Prof. Dewar has, during the year, continued his experiments on the liquefaction of oxygen and nitrogen on a large scale. To a physicist perhaps the most important results of the research are the discovery of the magnetic properties of liquid oxygen, and the proof of the fact that the resistance of certain pure metals vanishes at absolute zero (*Phil. Mag.*, October, 1892). The last discovery is borne out by Griffiths and Callendar's experiments with their platinum thermometers (*Phil. Mag.*, December, 1892).

Mr. Williams's article on "The Relation of the Dimensions of Physical Quantities to Directions in Space" (*Phil. Mag.*, September, 1892) has led to an interesting discussion. Some of his deductions will be noticed later.

The title-page of the first edition of Maxwell's "Electricity and Magnetism" bears the date 1873. This year, 1893, we welcome a third edition, edited by Maxwell's distinguished successor, and enriched by a supplementary volume, in which Prof. J. J. Thomson describes some of the advances made by electrical science in the last twenty years. The subject matter of this volume might well serve as a text for a Presidential Address.

The choice of a subject on which to speak to-day has been no easy task. The field of physics and mathematics is a wide one. There is one matter, however, to which for a few minutes I should like to call your attention, inadequately though it be. Optical theories have, since the year 1876, when I first read Sir George Stokes's "Report on Double Refraction" (British Association Report, 1862), had a special interest for me, and I think the time has come when we may with advantage review our position with regard to them, and sum up our knowledge.[1]

That light is propagated by an undulatory motion through a medium which we call the ether is now an established fact, although we know but little of the nature or constitution of the ether. The history of this undulatory theory is full of interest, and has, it appears to me, in its earlier stages been not quite clearly apprehended. Two theories have been proposed to account for optical phenomena. Descartes was the author of the one, the emission theory. Hooke, though his work was very incomplete, was the founder of the undulatory theory. In his "Micrographia," 1664, page 56, he asserts that light is a quick and short vibratory motion, "propagated every way through an homogeneous medium by direct or straight lines extended every way like rays from the centre of a sphere. . . . Every pulse or vibration of the luminous body will generate a sphere which will continually increase and grow bigger, just after the same manner, though indefinitely swifter, as the waves or rings on the surface do swell into bigger and bigger circles about a point on it"; and he gives on this hypothesis an account of reflexion, refraction, dispersion, and the colours of thin plates. In the same work, page 58, he describes an experiment practically identical with Newton's famous prism experiment, published in 1672. Hooke used for a prism a glass vessel about two feet long, filled with water, and inclined so that the sun's rays might enter obliquely at the upper surface and traverse the water. "The top surface is covered by an opacous body, all but a hole through which the sun's beams are suffered to pass into the water, and are thereby refracted" to the bottom of the glass, "against which part if a paper be expanded on the outside there will appear all the colours of the rainbow—that is, there will be generated the two principal colours, scarlet and blue, with all the intermediate ones which arise from the composition and diluting of these two." But Hooke could make no use of his own observation; he attempted to substantiate from it his own theory of colours, and

[1] "In general," he says, "the satellite has been faint. . . . . On the 13th, however, when the air was very clear, it was quite easy."—NATURE, October 20, 1892.

[1] This address was in the printer's hands when I saw Sir George Stokes's paper on "The Luminiferous Ether," NATURE, July 27. Had I known that so great a master of my subject had dealt with it so lately, my choice might have been different; under the circumstances it was too late to change.

wrote pure nonsense in the attempt; and though his writings contain the germ of the theory, and in the light of our present knowledge it seems possible that he understood it more thoroughly than his contemporaries believed, yet his reasoning is so utterly vague and unsatisfactory that there is little ground for surprise that he convinced but few of its truth.

And then came Newton. It is claimed for him, and that with justice, that he was the true founder of the emission theory. In Descartes' hands it was a vague hypothesis. Newton deduced from it by rigid reasoning the laws of reflexion and refraction; he applied it with wondrous ingenuity to explain the colours of thin and of thick plates and the phenomena of diffraction, though in doing this he had to suppose a mechanism which he must have felt to be almost impossible; a mechanism which in time, as it was applied to explain other and more complex phenomena, became so elaborate that, in the words of Verdet, referring to a period one hundred years later, "all that is necessary to overturn this laborious scaffolding is to look at it and try to understand it."

But though Newton may with justice be called the founder of the emission theory, it is unjust to his memory to state that he accepted it as giving a full and satisfactory account of optics as they were known to him. When he first began his optical work he realised that facts and measurements were needed, and his object was to furnish the facts. He may have known of Hooke's theories. The copy of the "Micrographia" now at Trinity College was in the Library while Newton was working with his prism in rooms in college, and may have been consulted by him. An early note-book of his contains quotations from it. Still there was nothing in the theories but hypotheses unsupported by facts, and these would have no charm for Newton. The hypotheses in the main are right. Light is due to wave motion in an all-pervading ether; the principle of interference, vaguely foreshadowed by Hooke ("Micrographia," p. 66), was one which a century later was to remove the one difficulty which Newton felt. For there was one fact which Hooke's theory could not then explain, and till that explanation was given the theory must be rejected; the test was crucial, the answer was decisive.

Newton tells us repeatedly what the difficulty was. In reply to a criticism of Hooke's in 1672, he writes: "For to me the fundamental supposition itself seems impossible, namely, that the waves of vibrations of any fluid can, like the rays of light, be propagated in straight lines without continual and very extravagant spreading and bending into the quiescent medium where they are terminated by it. I mistake if there be not both experiment and demonstration to the contrary. . . . For it seems impossible that any of those motions or pressions can be propagated in straight lines without the like spreading every way into the shadowed medium."

Nor was there anything in the controversy with Hooke, which took place about 1675, to shake this belief. Hooke had read his paper describing his discovery of diffraction. He had announced it two years earlier, and there is no doubt in my mind that this was an original discovery, and not, as Newton seemed to imply soon after, taken from Grimaldi; but his paper does not remove the difficulty. Accordingly we find in the "Principia" Newton's attempted proof (lib. ii. prop. 42) that "motus omnis per fluidum propagatus divergit a recto tramite in spatia immota"—a demonstration which has convinced but few and leaves the question unsolved as before.

Again, in 1690 Huygens published his great "Traité de la Lumière," written in 1678. Huygens had clearer views than Hooke on all he wrote; many of his demonstrations may be given now as completely satisfactory, but on the one crucial matter he was fatally weak. He, rather than Hooke, is the true founder of the undulatory theory, for he showed what it would do if it could but explain the rectilinear propagation. The reasoning of the latter part of Huygens's first chapter becomes forcible enough when viewed in the light of the principle of interference enunciated by Young, November 12, 1801, and developed, independently of Young, by Fresnel in his great memoir on "Diffraction" in 1815; but without this aid it was not possible for Huygens's arguments to convince Newton, and hence in the "Opticks" (2nd edit., 1717) he wrote the celebrated Query 28: "Are not all hypotheses erroneous in which light is supposed to consist in pressure or motion propagated through a fluid medium? If it consisted in motion propagated either in an instant or in time it would bend into the shadow. For pressure or motion cannot be propagated in a fluid in right lines beyond an obstacle which stops part of the motion, but will bend and spread every way into the quiescent medium which lies outside the shadow." These were his last words on the subject. They prove that he could not accept the undulatory theory; they do not prove that he believed the emission theory to give the true explanation. Yet, in spite of this, I think that Newton had a clearer view of the undulatory theory than his contemporaries, and saw more fully than they did what that theory could achieve if but the one difficulty were removed.

This was Young's belief, who writes (*Phil. Trans.*, November 12, 1801):—"A more extensive examination of Newton's various writings has shown me that he was in reality the first who suggested such a theory as I shall endeavour to maintain; that his own opinions varied less from this theory than is now almost universally believed; and that a variety of arguments have been advanced as if to meet him which may be found in a nearly similar form in his own works." I wish to call attention to this statement, and to bring into more prominent view the grounds on which it rests, to place Newton in his true position as one of the founders of the undulatory theory.

The emission theory in Newton's hands was a dynamical theory; he traced the motion of material particles under certain forces, and found their path to coincide with that of a ray of light; and in the "Principia," prop. xcvi., Scholium, he calls attention to the similarity between these particles and light. The particles obey the laws of reflexion and refraction; but to explain why some of the incident light was reflected and some refracted Newton had to invent his hypothesis of fits of easy reflexion and transmission. These are explained in the "Opticks," book iii., props. xi., xii., and xiii. (1704), thus:—

"Light is propagated from luminous bodies in time, and spends about seven or eight minutes of an hour in passing from the sun to the earth.

"Every ray of light in its passage through any refracting surface is put into a certain transient constitution or state, which in the progress of the ray returns at equal intervals, and disposes the ray at each return to be easily transmitted through the next refracting surface, and between the returns to be easily reflected by it.

"*Definition.*—The return of the disposition of any ray to be reflected I will call its fit of easy reflexion, and those of the disposition to be transmitted its fits of easy transmission, and the space it passes between every return and the next return the interval of its fits.

"The reason why the surfaces of all thick transparent bodies reflect part of the light incident on them and refract the rest is that some rays at their incidence are in their fits of easy reflexion, some in their fits of easy transmission."

Such was Newton's theory. It accounts for some or all of the observed facts; but what causes the fits? Newton, in the "Opticks," states that he does not inquire; he suggests, for those who wish to deal in hypotheses, that the rays of light striking the bodies set up waves in the reflecting or refracting substance which move faster than the rays and overtake them. When a ray is in that part of a vibration which conspires with its motion, it easily breaks through the refracting surface—it is in a fit of easy transmission; and, conversely, when the motion of the ray and the wave are opposed, it is in a fit of easy reflexion.

But he was not always so cautious. At an earlier date (1675) he sent to Oldenburg, for the Royal Society, an "Hypothesis explaining the Properties of Light"; and we find from the journal book that "these observations so well pleased the society that they ordered Mr. Oldenburg to desire Mr. Newton to permit them to be published." Newton agreed, but asked that publication should be deferred till he had completed the account of some other experiments which ought to precede those he had described. This he never did, and the hypothesis was first printed in Birch's "History of the Royal Society," vol. iii., pp. 247, 262, 272, &c.; it is also given in Brewster's "Life of Newton," vol. i., App. II., and in the *Phil. Mag.*, September, 1846, pp. 187–213.

"Were I," he writes in this paper, "to assume an hypothesis, it should be this, if propounded more generally, so as not to assume what light is further than that it is something or other capable of exciting vibrations of the ether. First, it is to be assumed that there is an ethereal medium, much of the same constitution with air, but far rarer, subtiller, and more strongly elastic. . . . In the second place, it is to be supposed that the ether is a vibrating medium, like air, only the vibrations far more swift and minute; those of air made by a man's ordinary voice succeeding at more than half a foot or a foot distance, but those of ether at a less distance than the hundred-thousandth part of an inch. And as in air the vibrations are some larger than others, but yet all equally swift . . . so I suppose the ethereal vibrations differ in bigness but not in swiftness. . . . In the fourth place, therefore, I suppose that light is neither ether nor its vibrating motion, but something of a different kind propagated from lucid bodies. They that will may suppose it an aggregate of various peripatetic qualities. Others may suppose it multitudes of unimaginable small and swift corpuscles of various sizes springing from shining bodies at great distances one after the other, but yet without any sensible interval of time. . . . To avoid dispute and make this hypothesis general, let every man here take his fancy; only, whatever light be, I would suppose it consists of successive rays differing from one another in contingent circumstances, as bigness, force, or vigour, like as the sands on the shore . . . and, further, I would suppose it diverse from the vibrations of the ether. . . . Fifthly, it is to be supposed that light and ether mutually act upon one another." It is from this action that reflexion and refraction come about; "æthereal vibrations are therefore," he continues, "the best means by which such a subtile agent as light can shake the gross particles of solid bodies to heat them. And so, supposing that light impinging on a refracting or reflecting ethereal superficies puts it into a vibrating motion, that physical superficies being by the perpetual appulse of rays always kept in a vibrating motion, and the ether therein continually expanded and compressed by turns, if a ray of light impinge on it when it is much compressed, I suppose it is then too dense and stiff to let the ray through, and so reflects it; but the rays that impinge on it at other times, when it is either expanded by the interval between two vibrations or not too much compressed and condensed, go through and are refracted. . . . And now to explain colours. I suppose that as bodies excite sounds of various tones and consequently vibrations, in the air of various bignesses, so when the rays of light by impinging on the stiff refracting superficies excite vibrations in the ether, these rays excite vibrations of various bignesses . . . therefore, the ends of the capillamenta of the optic nerve which front or face the retina being such refracting superficies, when the rays impinge on them they must there excite these vibrations, which vibrations (like those of sound in a trumpet) will run along the aqueous pores or crystalline pith of the capillamenta through the optic nerves into the sensorium (which light itself cannot do), and there, I suppose, affect the sense with various colours, according to their bigness and mixture—the biggest with the strongest colours, reds and yellows; the least with the weakest, blues and violets; the middle with green; and a confusion of all with white."

The last idea, the relation of colour to the bigness of wave-length, is put even more plainly in the "Opticks," Query 13 (ed. 1704):—"Do not several sorts of rays make vibrations of various bignesses, which according to their bignesses excite sensations of various colours . . . and, particularly, do not the most refrangible rays excite the shortest vibrations for making a sensation of deep violet; the least refrangible the largest for making a sensation of deep red?"

The whole is but a development of a reply, written in 1672, to a criticism of Hooke's on his first optical paper, in which Newton says: "It is true that from my theory I argue the corporeity of light, but I do it without any absolute positiveness, as the word perhaps intimates, and make it at most a very plausible consequence of the doctrine, and not a fundamental supposition. Certainly," he continues, "my hypothesis has a much greater affinity with his own [Hooke's] than he seems to be aware of, the vibrations of the ether being as useful and necessary in this as in his."

Thus Newton, while in the "Opticks" he avoided declaring himself as to the mechanism by which the fits of easy reflexion and transmission were produced, has in his earlier writings developed a theory practically identical in many respects with modern views, though without saying that he accepted it. It was an hypothesis; one difficulty remained, it would not account for the rectilinear propagation, and it must be rejected till it did.

Light is neither ether nor its vibrating motion; it is energy which, emitted from luminous bodies, is carried by wave motion in rays, and falling on a reflecting surface sets up fresh waves by which it is in part transmitted and in part reflected. Light is not material, but Newton nowhere definitely asserts that it is. He "argues the corporeity of light, but without any absolute positiveness." In the "Principia," writing of his particles, his words are: "Harum attractionum haud multum dissimiles sunt Lucis reflexiones et refractiones"; and the Scholium concludes with "Igitur ob analogiam quæ est inter propagationem radiorum lucis et progressum corporum, visum est propositiones sequentes in usus opticos subjungere; interea de natura radiorum (utrum sint corpora necne) nihil omnino disputans, sed trajectorias corporum trajectoriis radiorum persimiles solummodo determinans."[1]

No doubt Newton's immediate successors interpreted his words as meaning that he believed in the corpuscular theory, conceived, as Herschel says, by Newton, and called by his illustrious name. Men learnt from the "Principia" how to deal with the motion of small particles under definite forces. The laws of wave motion were obscure, and till the days of Young and Fresnel there was no second Newton to explain them. There is truth in Whewell's words ("Inductive Sciences," ii. chap. x.): "That propositions existed in the 'Principia' which proceeded on this hypothesis was with many ground enough for adopting the doctrine." Young's view, already quoted, appears to me more just; and I see in Newton's hypothesis the first clear indication of the undulatory theory of light, the first statement of its fundamental laws.

Three years later (1678) Huygens wrote his "Traité de la Lumière," published in 1690. He failed to meet the main difficulty of the theory, but in other respects he developed its consequences to a most remarkable degree. For more than a century after this there was no progress, until in 1801 the principle of interference was discovered by Young, and again independently a few years later by Fresnel, whose genius triumphed over the difficulties to which his predecessors had succumbed, and, by combining the principles of interference and transverse vibrations, established an undulatory theory as a fact, thus making Newton's theory a *vera causa*.

There is, however, a great distinction between the emission theory as Newton left it and Fresnel's undulatory theory. The former was dynamical, though it could explain but little: the particles of light obeyed the laws of motion, like particles of matter. The undulatory theory of Huygens and Fresnel was geometrical or kinematical: the structure of the ether was and is unknown; all that was needed was that light should be due to the rapid periodic changes of some vector property of a medium capable of transmitting transverse waves. Fresnel, it is true, attempted to give a dynamical account of double refraction, and of the reflexion and refraction of polarised light, but the attempt was a failure; and not the least interesting part of Mr. L. Fletcher's recent book on double refraction ("The Optical Indicatrix") is that in which he shows that Fresnel himself in the first instance arrived at his theory by purely geometrical reasoning, and only attempted at a later date to give it its dynamical form. "If we reflect," says Stokes ("Report on Double Refraction," *Brit. Assoc Report*, 1862, p. 254), "on the state of the subject as Fresnel found it and as he left it, the wonder is, not that he failed to give a rigorous dynamical theory, but that a single mind was capable of effecting so much." Every student of optics should read Fresnel's great memoirs.

But the time was coming when the attempt to construct a dynamical theory of light could be made. Navier, in 1821, gave the first mathematical theory of elasticity. He limited himself to isotropic bodies, and worked on Boscovitch's hypothesis as to the constitution of matter. Poisson followed on the same lines, and the next year (1822) Cauchy wrote his first memoir on elasticity. The phenomena of light afforded a means of testing this theory of elasticity, and accordingly the first mechanical conception of the ether was that of Cauchy and Neumann, who conceived it to consist of distinct hard particles acting upon one another with forces in the line joining them, which vary as some function of the distances between the particles. It was now possible to work out a mechanical theory of light which should be a necessary consequence of these hy-

[1] The reflexions and refractions of light are not very unlike these attractions. Therefore, because of the analogy which exists between the propagation of rays of light and the motion of bodies, it seemed right to add the following propositions for optical purposes, not at all with any view of discussing the nature of rays (whether they are corporeal or not), but only to determine paths of particles which closely resemble the paths of rays.—"Principia," lib. i., sect. xiv., prop. xcvi., Scholium.

potheses. Cauchy's and the earlier theories do not represent the facts either in an elastic solid or in the ether. At present we are not concerned with the cause of this; we must recognise it as the first attempt to explain on a mechanical basis the phenomena observed. According to his theory in its final form, there are, in an isotropic medium, two waves which travel with velocities $\sqrt{A/\rho}$ and $\sqrt{B/\rho}$, A and B being constants and ρ the density. Adopting Cauchy's molecular hypothesis, there must be a definite relation between A and B.

A truer view of the theory of elasticity is given by Green in his paper read before the Cambridge Philosophical Society in 1837. This theory involves the two constants, but they are independent, and to account for certain optical effects A must either vanish or be infinite. The first supposition was, until a few years since, thought to be inconsistent with stability; the second leads to consequences which in part agree with the results of optical experiment, but which differ fatally from those results on other points. And so the first attempt to construct a mechanical theory of light failed. We have learnt much from it. At the death of Green the subject had advanced far beyond the point at which Fresnel left it. The causes of the failure are known, and the directions in which to look for modifications have been pointed out.

Now I believe that the effort to throw any theory into mechanical form, to conceive a model which is a concrete representation of the truth, to arrive at that which underlies our mathematical equations wherever possible, is of immense value to every student. Such a course, I am well aware, has its dangers. It may be thought that we ascribe to the reality all the properties of the model, that, in the case of the ether, we look upon it as a collection of gyrostatic molecules and springs, or of pulleys and indiarubber bands, instead of viewing it from the standpoint of Maxwell, who hoped, writing of his own model, "that by such mechanical fictions, anyone who understands the provisional and temporary character of his hypothesis will find himself helped rather than hindered in his search after the true interpretation of the phenomena." Prof. Boltzmann, in his most interesting paper on "The Methods of Theoretical Physics" (*Phil. Mag.*, July, 1893) has quoted these words, and has expressed far more ably than I can hope to do the idea I wish to convey.

The elastic solid theory, then, has failed; but are we therefore without any mechanical theory of light? Are we again reduced to merely writing down our equations, and calling some quantity which appears in them the amplitude of the light vibration, and the square of that quantity the intensity of the light? Or can we take a further step? Let us inquire what the properties of the ether must be which will lead us by strict reasoning to those equations which we know represent the laws of the propagation of light.

These equations resemble in many respects those of an elastic solid; let us, then, for a moment identify the displacement in a light-wave with an actual displacement of a molecule of some medium having properties resembling that of a solid. Then this medium must have rigidity or quasi-rigidity in order that it may transmit transverse waves; at the same time it must be incapable of transmitting normal waves, and this involves the supposition that the quantity A which appears in Green's equations must vanish or be infinite. To suppose it infinite is to recur to the incompressible solid theory; we will assume, therefore, that it is zero. Reflexion and refraction show us that the ether in a transparent medium such as glass differs in properties from that in air. It may differ either (1) in density or effective density,[1] or (2) in rigidity or effective rigidity. The laws of double refraction, and the phenomena of the scattering of light by small particles, show us that the difference is, in the main, in density or effective density; the rigidity of the ether does not greatly vary in different media. Dispersion, absorption, and anomalous dispersion all tell us that in some cases energy is absorbed from the light vibrations by the matter through which they pass, or, to be more general, by something very intimately connected with the matter.

We do not know sufficient to say what that action must be; we can, however, try the consequences of various hypotheses. Guided by the analogy of the motion of a solid in a fluid, let us assume that the action is proportional to the acceleration of the ether particles relative to the matter, and, further, that under certain circumstances some of the energy of the ether particles is transferred to the matter, thus setting them in vibration. If such action be assumed, the actual density of the ether may be the same in all media, the mathematical expression for the forces will lead to the same equations as those we obtain by supposing that there is a variation of density, and since it is clearly reasonable to suppose that this action between matter and ether is, in a crystal a function of the direction of vibration, the apparent or effective density of the ether in such a body will depend on the direction of displacement.

Now these hypotheses will conduct us by strict mathematical reasoning to laws for the propagation, reflexion and refraction, double refraction and polarisation, dispersion, absorption, and anomalous dispersion and aberration of light which are in complete accordance with the most accurate experiments.

The rotatory polarisation of quartz, sugar, and other substances points to a more complicated action between the ether and matter than is contemplated above; and, accordingly, other terms have to be introduced into the equations to account for these effects. It will be noted as a defect, and perhaps a fatal one, that the connection between electricity and light is not hinted at, but I hope to return to that point shortly.

Such a medium as I have described is afforded us by the labile ether of Lord Kelvin. It is an elastic solid or quasi-solid incapable of transmitting normal waves. The quantity A is zero, but Lord Kelvin has shown that the medium would still be stable provided its boundaries are fixed, or, which comes to the same thing, provided it extends to infinity. Such a medium would collapse if it were not held fixed at its boundaries; but if it be held fixed, and if then all points of any closed spherical surface in the medium receive a small normal displacement, so that the matter within the surface is compressed into a smaller volume, there will be no tendency either to aid or to prevent this compression, the medium in its new state will still be in equilibrium, the stresses in any portion of it which remains unaltered in shape are independent of its volume, and are functions only of the rigidity and, implicitly, of the forces which hold the boundary of the whole medium fixed.

A soap film affords in two dimensions an illustration of such a medium; the tension at any point of the film does not depend on the dimensions; we may suppose the film altered in area in any way we please—so long as it remains continuous—without changing the tension. Waves of displacement parallel to the surface of the film would not be transmitted. But such a film, in consequence of its tension, has an apparent rigidity for displacements normal to its surface: it can transmit transverse waves with a velocity which depends on the tension. Now the labile ether is a medium which has, in three dimensions, characteristics resembling those of the two-dimensional film. Its fundamental property is that the potential energy per unit volume, in an isotropic body, so far as it arises from a given strain, is proportional to the square of the resultant twist. In an incompressible elastic ether this potential energy depends upon the shearing strain. Given such a medium—and there is nothing impossible in its conception—the main phenomena of light follow as a necessary consequence. We have a mechanical theory by the aid of which we can explain the phenomena; we can go a few steps behind the symbols we use in our mathematical processes. Lord Kelvin, again, has shown us how such a medium might be made up of molecules having rotation in such a way that it could not be distinguished from an ordinary fluid in respect to any irrotational motion; it would, however, resist rotational movements with a force proportionate to the twist, just the force required; the medium has no real rigidity, but only a quasi-rigidity conferred on it by its rotational motion. The actual periodic displacements of such a medium may constitute light. We may claim, then, with some confidence, to have a mechanical theory of light.

But nowadays the ether has other functions to perform, and there is another theory to consider, which at present holds the field. Maxwell's equations of the electromagnetic field are practically identical with those of the quasi-labile ether. The symbols which occur can have an electromagnetic meaning; we speak of permeability and inductive capacity instead of rigidity and density, and take as our variables the electric or magnetic displacements instead of the actual displacement or the rotation.

[1] The equations of motion for a medium such as is supposed above can be written—

$\rho \times$ acceleration of ether $+ \rho' \times$ acceleration of matter $= \Sigma$ B $\times$ function of ether displacements, and their differential coefficients with respect to the co-ordinates $+ \Sigma$ B$' \times$ similar function for matter displacements.

The quantity ρ may be spoken of as the effective ether density, the quantities B as the effective elasticity or rigidity.

Still such a theory is not mechanical. Electric force acts on matter charged with electricity, and the ratio of the force to the charge can be measured in mechanical units. A fundamental conception in Maxwell's theory is electric displacement, and this is proportional to the electric force. Moreover, its convergence measures the quantity of electricity present per unit volume; but we have no certain mechanical conception of electric displacement or quantity of electricity, we have no satisfactory mechanical theory of the electromagnetic field. The first edition of the "Electricity and Magnetism" appeared twenty years ago. In it Maxwell says: "It must be carefully borne in mind that we have made only one step in the theory of the action of the medium. We have supposed it to be in a state of stress, but we have not in any way accounted for this stress or explained how it is maintained. This step, however, appears to me to be an important one, as it explains by the action of consecutive parts of the medium phenomena which were formerly supposed to be explicable only by direct action at a distance. I have not been able to make the next step, namely, to account by mechanical considerations for these stresses in the dielectric." And these words are true still.

But, for all this, I think it may be useful to press the theory of the quasi-labile ether as far as it will go, and endeavour to see what the consequences must be.

The analogy between the equations of the electromagnetic field and those of an elastic solid has been discussed by many writers. In a most interesting paper on the theory of dimensions, read recently before the Physical Society, Mr. Williams has called attention to the fact that two only of these analogies have throughout a simple mechanical interpretation. These two have been developed at some length by Mr. Heaviside in his paper in the *Electrician* for January 23, 1891. To one of them Lord Kelvin had previously called attention ("Collected Papers," vol. iii. p. 450.)

Starting with a quasi-labile ether, then, we may suppose that μ, the magnetic permeability of the medium, is $4\pi\rho$,[1] where ρ is the density, and that K, the inductive capacity, is $1/4\pi B$. B being the rigidity, or the quasi-rigidity conferred by the rotation.

The kinetic energy of such a medium is $\frac{1}{2}\rho(\dot\xi^2 + \dot\eta^2 + \dot\zeta^2)$, where $\dot\xi$, $\dot\eta$, $\dot\zeta$ are the components of the displacement. Let us identify this with the electromagnet energy $(\alpha^2 + \beta^2 + \gamma^2)8\pi$, α, β, γ being components of the magnetic force, so that $\alpha = \dot\xi$, $\beta = \dot\eta$, $\gamma = \dot\zeta$. Then the components of the electric displacement, assuming them to be zero initially, are given by

$$f = \frac{1}{4\pi}\left(\frac{d\zeta}{dy} - \frac{d\eta}{dz}\right), \text{ \&c.};$$

that is, the electric displacement $\mathfrak{D}$ multiplied by 4π is equal to the rotation in the medium. Denote this by Ω.

The potential energy due to the strain is

$$\tfrac{1}{2}B\Omega^2, \text{ or } \tfrac{1}{2}16\pi^2 B\mathfrak{D}^2,$$

and on substituting for B this becomes

$$\frac{1}{2}\frac{4\pi}{K}\mathfrak{D}^2,$$

which is Maxwell's expression for the electrostatic energy of the field.

Thus so far, but no farther, the analogy is complete; the kinetic energy of the medium measures the magnetic energy, the potential energy measures the electrostatic energy. The stresses in the ether, however, are not those given by Maxwell's theory.

In the other form of the analogy we are to take the inductive capacity as $4\pi\rho$ and the magnetic permeability as $1/4\pi B$. The velocity measures the electric force, and the rotation the magnetic force, so that electrostatic energy is kinetic, and magnetic energy potential. Such an arrangement is not so easy to grasp as the other. Optical experiments, however, show us that in all probability it is ρ, and not B, which varies, while from our electrical measurements we know that K is variable and μ constant; hence this is a reason for adopting the second form.

In either case we look upon the field as the seat of energy distributed per unit of volume according to Maxwell's law. The total energy is obtained by integration throughout the field.

[1] If we adopted Mr. Heaviside's rational system of units the 4π would disappear.

Now we can transform this integral by Green's theorem to a surface integral over the boundary, together with a volume integral through the space; and the form of these integrals shows us that we may look upon the effects, dealing for the present with electrostatics only, as due to the attractions and repulsions of a certain imaginary matter distributed according to a definite law over the boundary and throughout the space. To this imaginary matter, then, in the ordinary theory we give the name of Electricity.

Thus an electrified conducting sphere, according to these analogies, is not a body charged with a quantity of something we call electricity, but a surface at which there is a discontinuing in the rotation impressed upon the medium, or in the flow across the surface; for in the conductor a viscous resistance to the motion takes the place of rigidity. No permanent strain can be set up.

From this standpoint we consider electrical force as one of the manifestations of some action between ether and matter. There are certain means by which we can strain the ether: the friction of two dissimilar materials, the chemical action in a cell are two; and when, adopting the first analogy, this straining is of such a nature as to produce a rotational twist in the ether, the bodies round are said to be electrified; the energy of the system is that which would arise from the presence over their surfaces of attracting and repelling matter, attracting or repelling according to the inverse square law. We falsely assign this energy to such attractions instead of to the strains and stresses in the ether.

Such a theory has many difficulties. It is far from being proved; perhaps I have erred in trespassing on your time with it in this crude form. The words of the French *savant*, quoted by Poincaré, will apply to it: "I can understand all Maxwell except what he means by a charged body." It is not, of course, the only hypothesis which might be formed to explain the facts, perhaps not even the most probable. For many points the vortex sponge theory is its superior. Still I feel confident that in time we shall come to see that the phenomena of the electro-magnetic field may be represented by some such mechanism as has been outlined, and that confidence must be my excuse for having ventured to call your attention to the subject.

SECTION B.

CHEMISTRY.

OPENING ADDRESS BY PROF. EMERSON REYNOLDS, M.D., SC.D., F.R.S., PRESIDENT OF THE SECTION.

AT the Nottingham Meeting of the British Association in 1866, Dr. H. Bence Jones addressed the Section over which I have now the honour to preside on the place of Chemical Science in Medical Education. Without dwelling on this topic to-day, it is an agreeable duty to acknowledge the foresight of my predecessor as to the direction of medical progress. Twenty-seven years ago the methods of inquiry and instruction in medicine were essentially based on the formal lines of the last generation. Dr. Bence Jones saw that modern methods of research in chemistry—and in the experimental sciences generally—must profoundly influence medicine, and he urged the need of fuller training of medical students in those sciences.

The anticipated influence is now operative as a powerful factor in the general progress of medicine and medical education; but much remains to be desired in regard to the chemical portion of that education. In the later stages of it, undue importance is still attached to the knowledge of substances rather than of principles; of products instead of the broad characters of the chemical changes in which they are formed. Without this higher class of instruction it is unreasonable to expect an intelligent perception of complex physiological and pathological processes which are chemical in character, or much real appreciation of modern pharmacological research. I have little doubt, however, that the need for this fuller chemical education will soon be so strongly felt that the necessary reform will come from within a profession which has given ample proof in recent years of its zeal in the cause of scientific progress.

In our own branch of science the work of the year has been substantial in character, if almost unmarked by discoveries of popular interest. We may probably place in the latter category the measure of success which the skill of Moissan has enabled him to attain in the artificial production of the diamond form of carbon, apparently in minute crystals similar to those recognised by Koenig, Mallard, Daubrée, and by Friedel in the supposed meteorite of Cañon de Diablo in Arizona. Members of the Section will probably have the opportunity of examining some of these artificial diamonds through the courtesy of M. Moissan, who has also, at my request, been so good as to arrange for us a demonstration of the properties of the element fluorine, which he succeeded in isolating in 1887.

Not less interesting or valuable are the studies of Dr. Perkins, on electro-magnetic rotation; of Lord Rayleigh, on the relative densities of gases; of Dewar, on chemical relations at extremely low temperatures; of Clowes, on exact measurements of flame-cap indications afforded by miners' testing lamps; of Horace Brown and Morris, on the chemistry and physiology of foliage leaves, by which they have been led to the startling conclusion that cane-sugar is the first sugar produced during the assimilation of carbon, and that starch is formed at its expense as a more stable reserve material for subsequent use of the plant; or of Cross, Bevan, and Beadle, on the interaction of alkali-cellulose and carbon bisulphide, in the course of which they have proved that a cellulose residue can act like an alcohol radical in the formation of thiocarbonates, and thus have added another to the authors' valuable contributions to our knowledge of members of the complex group of celluloses.

But it is now an idle task for a President of this Section to attempt a slight sketch of the works of chemical philosophers even during the short space of twelve months; they are too numerous and generally too important to be lightly treated, hence we can but apply to them a paraphrase of the ancient formula—Are they not written in the books of the chronicles we term "Jahresberichte," "Annales," or "Transactions and Abstracts," according to our nationality?

I would, however, in this connection ask your consideration for a question relating to the utilisation of the vast stores of facts laid up—some might even say buried—in the records to which reference has just been made. The need exists, and almost daily becomes greater, for facile reference to this accumulated wealth, and of such a kind that an investigator, commencing a line of inquiry with whose previous history he is not familiar, can be certain to learn *all* the facts known on the subject up to a particular date, instead of having only the partial record to be found in even the best edited of the dictionaries now available. The best and most obvious method of attaining this end is the publication of a subject-matter index of an ideally complete character. I am glad to know that the Chemical Society of London will probably provide us in the years to come with a compilation which will doubtless aim at a high standard of value as a work of reference to memoirs, and in some degree to their contents, so far as the existing indexes of the volumes of the Society's Journal supply the information. Whether this subject-matter index is published or not, the time has certainly arrived for adopting the immediately useful course of publishing monographs, analogous to those now usual in Natural Science, which shall contain all the information gained up to a particular date in the branch of chemistry with which the author is specially familiar by reason of his own work in the subject. Such monographs should include much more than any mere compilation, and would form the best material from which a complete subject-matter index might ultimately be evolved.

My attention was forcibly drawn to the need of such special records by noting the comparatively numerous cases of re-discovery and imperfect identification of derivatives of thiourea. In my laboratory, where this substance was isolated, we naturally follow with interest all work connected with it, and therefore readily detect lapses of the kind just mentioned. But when it is remembered that the distinct derivatives of thiourea now known number considerably over six hundred substances, and that their descriptions are scattered through numerous British and foreign journals, considerable excuse can be found for workers overlooking former results. The difficulty which exists in this one small department of the science I hope shortly to remove, and trust that others may be induced to provide similar works of reference to the particular branches of chemistry with which they are personally most familiar.

When we consider the drift of investigation in recent years, it is easy to recognise a distinct reaction from extreme specialisation in the prominence now given to general physico-chemical problems, and to those broad questions concerning the relations of the elements which I would venture to group under the head of "Comparative Chemistry." Together these lines of inquiry afford promise of definite information about the real nature the seventy or more entities we term "elements," and ab the mechanism of that mysterious yet definite change in ma which we call "chemical action." Now and again one or ot class of investigation enables us to get some glimpse beyond known which stimulates the imaginative faculty.

For example, a curious side-light seems to be thrown on nature of the elements by the chemico-physical discussion the connection existing between the constitution of certain ganic compounds and the colours they exhibit. Without tempting to intervene in the interesting controversy in wh Armstrong and Hartly are engaged as to the nature of connection, we may take it as an established fact that a relat exists between the power which a dissolved chemical compo possesses of producing the colour impression within our co paratively small visual range, and the particular mode of gro ing of its constituent radicals in its molecule. Further, reality of this connection will be most freely admitted in class of aromatic compounds; that is, in derivatives of benze whose constituents are so closely linked together as to exh quasi-elemental persistence. If then, the possession of what call colour by a compound be connected with its constituti may we not infer that "elements" which exhibit disti colour, such as gold and copper, in thin layers and in t soluble compounds, are at least complexes analogous to definit decomposable substances? This inference, while legitimate it stands, would obviously acquire strength if we could sh that anything like isomerism exists among the elements; identity of atomic weight of any two chemically distinct e ments must, by all analogy with compounds, imply dissimila in constitution, and, therefore, definite structure, independen of any argument derived from colour. Now, nickel and cob are perfectly distinct elements, as we all know, but, so far existing evidence goes, the observed differences in their ato weights (nickel 58·6, cobalt 58·7) are so small as to be wit the range of the experimental errors to which the determinati were liable. Here, then, we seem to have the required exam of something like isomerism among elements, and consequen some evidence that these substances are complexes of differ orders; but in the cases of cobalt and nickel we also know t in transparent solutions of their salts, if not in thin layers of metals themselves, they exhibit strong and distinct colour compare the beautiful rosy tint of cobalt sulphate with the b liant green of the corresponding salt of nickel. Therefore, exhibiting characteristically different colours, these substan afford us some further evidence of structural differences betw the matter of which they consist, and support the conclusion which their apparent identity in atomic weight would lead By means of such side-lights we may gradually acquire so idea of the nature of the elements, even if we are unable to any clue to their origin other than such as may be found Crookes' interesting speculations.

Again, while our knowledge of the genesis of the chemi elements is as small as astronomers possess of the origin of t heavenly bodies, much suggestive work has recently be accomplished in the attempt to apply the principle of gravitati which simply explains the relative motions of the planets, account for the interactions of the molecules of the elemen The first step in this direction was suggested by Mendeleef in Royal Institution lecture (May 31, 1889) wherein he propos to apply Newton's third law of motion to chemical molecul regarded as systems of atoms analagous to double stars. T Rev. Dr. Haughton has followed up this idea with his we known mathematical skill, and, in a series of papers just pu lished, has shown that the three Newtonian laws are applica to explain the interactions of chemical molecules, "with t difference, that whereas the specific coefficient of gravity is same for all bodies, independent of the particular kind matter of which they are composed, the atoms have speci coefficients of attraction which vary with the nature the atoms concerned." The laws of gravitation, with t proviso, were found to apply to all the definite cases examin and it was shown that a chemical change of combination equivalent to a planetary catastrophe. So far the fundamen hypothesis of "Newtonian Chemistry" has led to conclusi which are not at variance with the facts of the science, whil gives promise of help in obtaining a solution of the great probl of the nature of chemical action.

Passing from considerations of the kind to which I have j referred, permit me to occupy the rest of the time at my posal with a short account of a line of study in what I have already termed "comparative chemistry," which is not only of inherent interest, but seems to give us the means of filling in some details of a hitherto rather neglected chapter in the early chemical history of this earth.

The most remarkable outcome of "comparative chemistry" is the periodic law of the elements, which asserts that the properties of the elements are connected in the form of a periodic function with the masses of their atoms. Concurrently with the recognition of this principle, other investigations have been in progress, aiming at more exact definitions of the characters of the relations of the elements, and ultimately of their respective offices in nature. Among inquiries of this kind the comparative study of the elements carbon and silicon appears to me to possess the highest interest. Carbon, whether combined with hydrogen, oxygen, or nitrogen, or with all three, is the great element of organic nature, while silicon, in union with oxygen and various metals, not only forms about one-third of the solid crust of the earth, but is unquestionably the most important element of inorganic nature. The chief functions of carbon are those which are performed at comparatively low temperatures; hence carbon is essentially the element of the present epoch. On the other hand, the activities of silicon are most marked at very high temperatures; hence it is the element whose chief work in nature was performed in the distant past, when the temperature of this earth was far beyond that at which the carbon compounds of organic life could exist. Yet between these dominant elements of widely different epochs remarkably close analogies are traceable, and the characteristic differences observed in their relations with other elements are just those which enable each to play its part effectively under the conditions which promote its greatest activity.

The chemical analogies of the two tetrad elements carbon and silicon are most easily recognised in compounds which either do not contain oxygen, or which are oxygen compounds of a very simple order, and the following table will recall a few of the most important of these, as well as some which have resulted from the fine researches of Friedel, Crafts, and Ladenburg:—

Some Silicon Analogues of Carbon Compounds.

SiH_4	Hydrides ...	... CH_4
$SiCl_4$	Chlorides	... CCl_4
Si_2Cl_6	Chlorides	... C_2Cl_6
SiO_2	Oxides ...	... CO_2
H_2SiO_3	Meta Acids	... H_2CO_3
$HSiHO_2$	Formic Acids	... $HCHO_2$
$(SiHO)_2O$	Formic Anhydrides	$(CHO)_2O$?
$H_2Si_2O_4$	Oxalic Acids	... $H_2C_2O_4$
$HSi(CH_3)O_2$ ...	Acetic Acids	... $HC(CH_3)O_2$
$HSi(C_6H_5)O_2$ ...	Benzoic Acids	... $HC(C_6H_5)O_2$
$SiC_8H_{19}H$	Nonyl Hydrides	... $C_9H_{19}H$
$SiC_8H_{19}OH$ ...	Nonyl Alcohols	... $C_9H_{19}OH$

But these silicon analogues of carbon compounds are, generally, very different from the latter in reactive power, especially in presence of oxygen and water. For example, hydride of silicon, even when pure, is very easily decomposed, and, if slightly warmed, is spontaneously inflammable in air; whereas the analogous marsh gas does not take fire in air below a red heat. Again, the chlorides of silicon are rapidly attacked by water affording silicon hydroxides and hydrochloric acid; but the analogous carbon chlorides are little affected by water even at comparatively high temperatures. Similarly, silicon-chloroform and water quickly produce silico-formic acid and anhydride along with hydrochloric acid, while ordinary chloroform can be kept in contact with water for a considerable time without material change.

Until recently no well-defined compounds of silicon were known including nitrogen; but we are now acquainted with a number of significant substances of this class.

Chemists have long been familiar with the fact that a violent reaction takes place when silicon chloride and ammonia are allowed to interact. Persoz, in 1830, assumed that the resulting white powder was an addition compound, and assigned to it the formula $SiCl_4$, 6 NH_3, while Besson, as lately as 1892, gave $SiCl_4$, 5 NH_3. These formulæ only express the proportions in which ammonia reacts with the chloride under different conditions and give us no information as to the real nature of the product; hence they are almost useless. Other chemists have, however, carefully examined the product of this reaction, but owing to peculiar difficulties in the way have not obtained results of a very conclusive kind. It is known that the product when strongly heated in a current of ammonia gas affords ammonium chloride, which volatilises, and a residue, to which Schutzenberger and Colson have assigned the formula Si_2N_3H. This body they regard as a definite hydride of Si_2N_3, which latter they produced by acting on silicon at a white heat with pure nitrogen. Gattermann suggests that a nearer approach to the silicon analogue of cyanogen, Si_2N_2, should be obtained from the product of the action of ammonia on silicon-chloroform; but it does not appear that this suggestion has yet borne fruit. It was scarcely probable that the above-mentioned rather indefinite compounds of silicon with nitrogen were the only ones of the class obtainable, since bodies including carbon combined with nitrogen are not only numerous but are among the most important carbon compounds known. Further investigation was therefore necessary in the interests of comparative chemistry, and for special reasons which will appear later on; but it was evident that a new point of attack must be found.

A preliminary experimental survey proved the possibility of forming numerous compounds of silicon containing nitrogen, and enabled me to select those which seemed most likely to afford definite information. For much of this kind of work silicon chloride was rather too energetic, hence I had a considerable quantity of the more manageable silicon tetrabromide prepared by Serullas' method, viz. by passing the vapour of crude bromine (containing a little chlorine) over a strongly heated mixture of silica and charcoal. In purifying this product I obtained incidentally the chloro-bromide of silicon, $SiClBr_3$, which was required in order to complete the series of possible chlorobromides of silicon.[1]

Silicon bromide was found to produce addition compounds very readily with many feebly basic substances containing nitrogen. But one group of bromides of this class has yet been investigated in detail, namely, the products afforded by thioureas. The typical member of this group is the perfectly definite but uncrystalline substance

$$SiBr_2\begin{cases}(CSN_2H^4)_4Br\\(CSN_2H_4)_4Br\end{cases}$$

Substituted thioureas afford similar bodies, the most interesting of which is the allyl compound. This is a singularly viscid liquid, which requires several days at ordinary temperatures to regain its level, when a tube containing it is inverted. But these are essentially addition compounds, and are therefore comparatively unimportant.

In most cases, however, the silicon haloids enter into very definite reaction with nitrogen compounds, especially when the latter are distinctly basic, such as aniline or any of its homologues. One of the principal products of this class of change is the beautiful typical substance on the table, which is the first well-defined crystalline compound obtained in which silicon is exclusively combined with nitrogen. Its composition is $Si(NHC_6H_5)_4$.[2] Analogous compounds have been formed with the toluidines, naphthylamines, &c., and have been examined in considerable detail, but it suffices to mention them and proceed to point out the nature of the changes we can effect by the action of heat on the comparatively simple anilide.

When silicon anilide is heated carefully *in vacuo* it loses one molecule of aniline very easily and leaves triphenyl-guanidine, probably the *a* modification; if the action of heat be continued, but at ordinary pressure and in a current of dry hydrogen, another molecule of aniline can be expelled, and, just before the last trace of the latter is removed, the previously liquid substance solidifies and affords a silicon analogue of the insoluble modification of carbodiphenyldiimide, which may then be heated moderately without undergoing further material change. A comparison of the formulæ will make the relations of the products clear:—

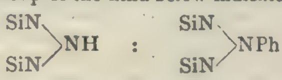
Silicotetraphenylamide—$Si(NHPh)_4$
Silicotriphenylguanidine—$Si : NPh . (NHPh)_2$
Silicodiphenyldiimide—$Si : (NPh)_2$.

Moreover, the diimide has been heated to full redness in a gas combustion furnace while dry hydrogen was still passed over it; even under these conditions little charring occurred, but some

[1] Three years later Besson formed the same compound, and described it as new.

[2] Harden has obtained an uncrystalline intermediate compound, $SiCl_2(NHC_6H_5)_2$.

nitrogen and a phenyl radical were eliminated, and the purified residue was found to approximate in composition to SiNPh, which would represent the body as phenylsilicocyanide or a polymer of it. Even careful heating of the diimide in ammonia gas has not enabled me to remove all the phenyl from the compound, but rather to retain nitrogen, as the best residue obtained from such treatment consisted of Si_2N_3Ph, or the phenylic derivative of one of the substances produced by Schutzenberger and Colson from the ammonia reaction. It may be that both these substances are compounds of silicocyanogen with an imide group of the kind below indicated—



Further investigation must decide whether this is a real relationship; if it be, we should be able to remove the imidic group and obtain silicocyanogen in the free state. One other point only need be noticed, namely, that when the above silicon compounds are heated in oxygen they are slowly converted into SiO_2; but the last traces of nitrogen are removed with great difficulty, unless water-vapour is present, when ammonia and silica are quickly formed.

Much remains to be done in this department of comparative chemistry, but we may fairly claim to have established the fact that silicon, like carbon, can be made to form perfectly well-defined compounds in which it is exclusively united with the triad nitrogen of amidic and imidic groups.

Now, having proved the capacity of silicon for the formation of compounds of this order with a triad element, Nature very distinctively lets us understand that nitrogen is not the particular element which is best adapted to place the triad *rôle* towards silicon in its high-temperature changes, which are ultimately dominated by oxygen. We are not acquainted with any natural compounds which include silicon and nitrogen; but large numbers of the most important minerals contain the pseudo-triad element aluminum combined with silicon, and few include any other triad. Phosphorus follows silicon in the periodic system of the elements as nitrogen does carbon, but silicates containing more than traces of phosphorus are rare; on the other hand, silicates are not uncommon containing boron, the lower homologue of aluminum; for example, axinite, datholite, and tourmaline.

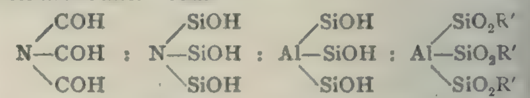
Moreover, it is well known that silicon dissolves freely in molten aluminum, though much more of the former separates on cooling. Winkler has analysed the gangue of aluminum saturated with silicon, and found that its composition is approximately represented by the formula SiAl, or, perhaps, Si_2Al_2, if we are to regard this as analogous to C_2N_2 or cyanogen. Here aluminum at least resembles nitrogen in directly forming a compound with silicon at moderately high temperature. It would appear, then, that while silicon can combine with both the triads nitrogen and aluminum, the marked positive characters of the latter, and its extremely low volatility, suit it best for the production of permanent silicon compounds similar to those which nitrogen can afford.

With these facts in mind we may carry our thoughts back to that period in the earth's history when our planet was at a higher temperature than the dissociation point of oxygen compounds. Under such conditions the least volatile elements were probably liquids, while silicides and carbides of various metals were formed in the fluid globe. We can imagine that the attraction of aluminum for the large excess of silicon would assert itself, and that, as the temperature fell below the point at which oxidation become possible, these silicides and carbides underwent some degree of oxidation, the carbides suffering most owing to the volatility of the oxides of carbon, while the fixity of the products of oxidation of silicides rendered the latter process a more gradual one. The oxidation of silicides of metals which had little attraction for silicon would lead to the formation of simple metallic silicates and to the separation of the large quantities of free silica we meet with in the solid crust of the earth, whereas oxidation of silicides of aluminum would not break up the union of the two elements, but rather cause the ultimate formation of the alumino-silicates which are so abundant in most of our rocks.

Viewed in the light of the facts already cited and the inferences we have drawn from them as to the nitrogen-like relationship of aluminum to silicon, I am disposed to regard the natural alumino-silicates as products of final oxidation of sometime active silico-aluminum analogues of carbo-nitrogen compounds rather than ordinary double salts. It is generally taken for granted that they are double salts, but recent work on the chromoxalates by E. A. Werner has shown that this view is not necessarily true of all such substances.

Without going into undue detail we can even form some conception of the general course of change from simple aluminum silicide to an alumino-silicate, if we allow the analogies already traced to lead us further.

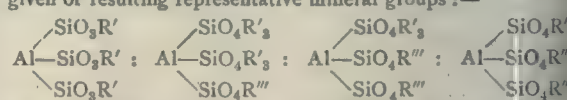
We recognise the existence of silico-formyl in Friedel and Ladenburg's silico-formic anhydride; hence silico-triformamide is a compound whose probable formation we can admit, and, on the basis of our aluminum-nitrogen analogy, an aluminum representative also. Thus—



Triformamide. Silico-triformamide. Silico-alumino-triformamide. Salt of an alumino-silicic acid.

Now, oxidation of triformamide would lead to complete resolution into nitrogen gas, carbondioxide gas and water rendering it an extremely unstable body; under similar conditions silico-triformamide would probably afford nitrogen gas and silicic acid (or silicon dioxide and water); while the third compound,[1] instead of breaking up, would (owing to the fixity of aluminum as compared with nitrogen) be likely at first to afford a salt of an alumino-silicic acid, in presence of much basic material.

The frequent recurrence of the ratios Si_3Al, Si_3Al_2, &c., in the formulæ of natural alumino-silicates, suggests that some at least of these minerals are derived from oxidation products of the above triformic type. Without stopping to trace all the possible stages in the oxidation of the primary compound $Al(SiO_3R)_3$, or variations in basicity of the products, I may cite the four following examples out of many others which might be given of resulting representative mineral groups:—



Beryl type (hemi-). Garnet type. Muscovite type. Xenolite type.

Five years ago Prof. F. W. Clarke, of the United States Geological Survey, published a most interesting paper on the structure of the natural silicates. In this he adopts the view that the mineral xenolite, $Si_3Al_4O_{12}$, is the primary from which all other alumino-silicates may be supposed to arise by various substitutions. Nature, however, seems to teach us that such minerals as xenolite, fibrolite, and the related group of "clays" are rather to be regarded as end-products of a series of hydrolytic changes of less aluminous silicates than primary substances themselves; hence the sketch which I have ventured to give above of the probable genesis of alumino-silicates seems to provide a less arbitrary basis for Clarke's interesting work, without materially disturbing the general drift of his subsequent reasoning.

We may now consider for a moment in what direction evidence can be sought for the existence in nature of derivatives of the hypothetical intermediate products of oxidation between a primary silicide and its fully oxidised silicate.

In the absence of a working hypothesis of the kind which I have already suggested it is not probable that direct evidence would yet be obtainable—this must be work for the future—but when we consider that the existence of compounds of the order in question would manifest themselves in ordinary mineral analyses by the analytical products exceeding the original weight of material, we seem to find some evidence on the point in recorded cases of the kind. A deficiency of a single atom of oxygen in compounds having the high molecular weights of those in question, would be indicated by very small excesses (from 2 to 3 per cent.) whose real meaning might be easily overlooked. Now, such results are not at all unusual in analyses of mineral alumino-silicates. For instance, *Amphibole* containing a mere trace of iron have afforded 102·75 parts from 100, and almost all analyses of *Microsommite* are high, giving as much as 103 parts. In less degree *Vesuvianite* and members of

[1] In these cases where R‴ = Al it is, of course, assumed that the latter is acting only as a basic radical.

the *Andalusite* group may be noted. All these cases may be capable of some other explanations, but I cite them to show that such excesses are commonly met with in published analyses. On the other hand, it is scarcely to be doubted that a good analyst, who obtained a really significant excess, would throw such a result aside as erroneous and never publish it. I therefore plead for much greater care in analyses of the kind in question, and closer scrutiny of results in the light of the suggestions I have ventured to offer. It is probable that silicates containing only partially oxidised aluminum are rare; nevertheless the search for them would introduce a new element of interest into mineralogical inquiries.

If the general considerations I have now endeavoured to lay before you are allowed their full weight, some of the alumino-silicates of our primary rocks reveal to us more than we hitherto supposed. Regarded from this newer standpoint, they are teleoxidised representatives of substances which foreshadowed in terms of silicon, aluminum, and oxygen the compounds of carbon, nitrogen, and hydrogen required at a later stage of the earth's history for living organisms. Thus, while the sedimentary strata contain remains which come down to us from the very dawn of life on this globe, the rocks from whose partial disintegration the preserving strata resulted contain mineral records which carry us still further back, even to Nature's earliest efforts in building up compounds similar to those suited for the purposes of organic development.

NOTES.

Prof. Max Müller has attained the jubilee of his Doctorate, having taken his degree in 1843, and in honour of the occasion the University of Leipzig has conferred a new diploma upon him.

Mr. Bell, of Carlton Street, Nottingham, has brought out, at an opportune moment, "A Contribution to the Geology and Natural History of Nottinghamshire." The little volume is edited by Mr. J. W. Carr, who in his preface records his indebtedness to various friends—specialists in certain departments—who wrote for him some portions of the book. The book was compiled at the request of the Local Excursions' Committee of the British Association, for the use of members attending the Nottingham meeting. We have no doubt that many such will avail themselves of the handy little guide-book, which has been prepared for their special benefit.

There seems to be no doubt that the latest report of the death of Emin Pasha is to be relied upon. Mr. A. J. Swann, of Ujiji, from whom the report comes, declares that in his opinion it is as conclusive as anything can be in Africa. And now within a week of the tidings of Emin's death the sudden decease is announced of another African traveller—Surgeon-Major Parke—one of the most widely-known of the members of the Emin Relief Expedition. He died suddenly on the night of Sunday last, while on a visit to the seat of the Duke of St. Albans at Alt-na-Craig.

The death is announced, at the age of sixty-one, of Dr. Alexander Strauch, the Director of the Zoological Museum of St. Petersburg. Dr. Strauch was an authority on reptiles, and the author of several zoological works.

The death is reported of Mr. T. W. Kennard, C.E., founder of the Monmouthshire Crumlin Works, designer and constructor of the Crumlin Viaduct, and engineer-in-chief of the Atlantic and Great Western Railway, United States. He died at the age of 68.

We have to record the death of a well-known inventor and civil engineer of New York, in the person of Mr. Joseph Battin. He was in his 87th year.

On and after November 1 next, the railway time throughout the kingdom of Italy will, according to a recent Act of the Legislature, be regulated by the mean solar time of the 15th meridian east of Greenwich, this being the so-called Middle European time. The hours will be reckoned from midnight to midnight. The new time will be 11 minutes in advance of the mean solar time of Rome. It is expected that the other services and the Italian public generally will soon follow the example set by the railway stations.

M. D'Arsonval, in *Électricité* for August 24, describes some experiments which he has made on the effects of strong, alternating magnetic fields on animals, his results apparently being somewhat contradictory to those recently obtained in the Edison Laboratory. M. D'Arsonval's experiments were performed by means of coils wound on cylinders of cardboard, glass or wood, large enough to accommodate a man inside them when required. The solenoid thus formed constituted the path for the discharge of a condenser of two to twelve Leyden jars, arranged in two batteries with proper precautions for rendering the discharge oscillatory. The jars were charged periodically by a transformer, giving a current at about 15,000 volts, with a frequency of sixty per second. A lamp held with one terminal in each hand of a man standing within the solenoid, may then be raised by the induced currents to bright incandescence, while M. D'Arsonval asserts that considerable physiological effects are also produced. The method used to determination the strength of these alternating magnetic fields is very ingenious; it consists simply in inserting a mercurial thermometer in the field, and noting the rise of temperature produced by the Foucault currents in the mercury. A considerable rise is very quickly produced in the strongest fields, while for weaker fields a petroleum thermometer is employed, or an air thermometer the bulb of which contains a small copper tube.

Dr. W. S. Hedley, in an article in the *Lancet*, comments on M. D'Arsonval's work, and mentions some experiments of his own which seem to support the hypothesis that the harmlessness of high frequency alternating currents may be explained by the fact that in these cases there is "virtually no current strength"; *e.g*, a current of two amperes at 200 volts, if transformed up to 100,000 volts, cannot exceed in strength 0·004 ampere. Another factor concerned in the effect is the "concentration" of the current. Passing a current of high frequency and capable of keeping a 5-candle lamp glowing, through the body by means of copper cylinders held in the hands, produced no appreciable effect beyond a slight warming under the electrodes; using a half-crown as electrode on the forearm, the same negative result follows; with a shilling, there is a slight pricking effect, which becomes quite painful with a threepenny-piece substituted for the shilling, thus indicating that other factors have to be considered, as well as more frequency, in the discussion of the "harmlessness" of alternating currents.

The issue in a compact form of the interesting series of articles on "Sewage Purification in America," by M. N. Baker, which appeared in the *Engineering News* of New York last year, furnishes an important addition to our information on this complicated subject. The treatment of the sewage of thirty municipalities in the United States and Canada is given in detail, and the description further elucidated by no less than seventy-seven illustrations, including elaborate plans showing the various arrangement of purification, plant, &c. The little pamphlet of 196 pages is well printed and is provided with a copious index. That America has recently devoted much attention to the vexed question of the purification of sewage will be remembered by all who have had occasion to consult the admirable experimental work on the chemical and bacteriological aspects of this subject, conducted at the instigation and under the superintendence of the Massachusetts State Board of Health.

"CHEMICAL and Micro-Mineralogical Researches on the Upper Cretaceous Zones of the South of England" is the title of the thesis sent in by Dr. W. F. Hume for the recent D.Sc. examination at London University. This paper gives a large amount of information on the subject; the zones described being those established by Dr. C. Barrois. The notes refer chiefly to the chalk of the Isle of Wight and Dorsetshire, but they include numerous references to the chalk of other areas, especially to that of Folkestone. The author's researches incline him to the belief that most of the chalk was deposited in fairly deep water; thus differing from M. Cayeux, whose work in the north of France led him to infer a shallow water origin for the chalk of that area. The insoluble residue decreases in quantity as we ascend in the series, and is generally greater in the Isle of Wight than at Folkestone; the excess being especially apparent in the Cenomanian zones. All the Upper Cenomanian beds have undergone secondary silicification.

THE Geological Survey of France has now published rather more than one-half of the country on the scale of 1 : 80,000—138 streets out of a total of 259. An excellent general map on the scale of 1 : 1,000,000 was issued in 1889. The first street (No. 13) of the map of the scale of 1 : 320,000 has just been published. This map, which is a reduction of sixteen streets on the larger scale, has Paris nearly in the centre, and includes Honfleur and Liseaux on the west, Chateaudun and Sens on the south, Nogent and Dormans on the east, Rouen and Beauvais on the north. The tertiary and secondary rocks are well represented within this area, the Silurian, Ordovieian, Cambrian and pre-Cambrian occupying a small space in the south-west near Mamers. The clay with flints is shown by shading over the chalk. The freshwater and estuarine strata are indicated by shading over the colour denoting the geological formations. Nnmerous notes on economic geology are printed below the map.

AN interesting study of the compounds of phosphorus and sulphur, by Herr Helff, is published in the current number of the *Zeitschrift für physikalische Chemie*. Hitherto seven sulphides of phosphorus have been described. Observations on vapour-density, and on the boiling-point of solutions in carbon bisulphide indicate, however, that four of these only are true chemical compounds, viz. P_4S_3, P_4S_7, P_3S_6, and P_2S_5. On heating two atomic proportions of phosphorus with three of sulphur, instead of P_2S_3 being formed it appears that the main product is P_4S_7, a little P_4S_3 being also obtained. The substances previously taken to be P_4S and P_4S_2 are merely solutions of sulphur in phosphorus. Incidentally the author confirms the results already arrived at by Beckmann, that when in solution in carbon bisulphide, sulphur has the molecular formula S_8 and phosphorus the formula P_4; he also shows that phosphorus and sulphur when dissolved in carbon bisulphide do not unite even on heating to the ordinary boiling-point. It is also noteworthy that the freezing-points of solutions of sulphur in phosphorus favour the view that here the molecular complexity of sulphur is the same as when it is dissolved in carbon bisulphide.

THE eighth meeting of the International Congress of Hygiene and Demography is to be held during the present month at Buda Pesth, and several international committees have, we understand, been formed with a view to carrying out the decisions of the London Congress. A separate section for tropical countries has been organised, and will meet under the presidency of Dr. Theodor Duka.

THE sixteenth annual meeting of the Library Association w held at Aberdeen on September 4 and 5. In his inaugural a dress, Dr. Garnett, Keeper of the Printed Books in the Britis Museum, dwelt upon the cataloguing of books. He said that catalogue should not merely enable the reader to find a boo with the least possible delay, but also present an epitome the life-work of every author, and assist the literary historia in his researches. Of the papers read, one by Prof. Trai on "The Classification of Books in the Natural Sciences," w of especial scientific interest.

SEVERAL very interesting lectures will shortly be delivered the evening meetings of the Camera Club. On September Prof. J. Milne, F.R.S., who is on a short visit from Japan, w discourse upon "The Earthquakes of Japan"; Mr. Lamo Howie will give a lecture, entitled "The Scottish Alps," September 28; and the October and November programm will include a paper by Prof. Marshall Ward, F.R.S.

THE Journal of the College of Science, Imperial Universit Japan, vol. vi. part 2, is devoted to a paper by Mr. Sadahi Matsuda on "The Anatomy of Magnoliaceæ." The auth splits up *Magnoliaceæ* into the four following groups: (1) Tho identical with *Magnolieæ*, (2) those identical with *Schizandr* (3) *Trochodendron* and the genera of *Illicieæ*, (4) *Eupteleæa* a *Cercidiphyllum*.

A REVISED report on the "Copepoda of Liverpool Bay by Mr. Isaac C. Thompson, has been published in the Tran actions of the Liverpool Biological Society, vol. vii. T report deals with 136 species, eighteen of which are new to t district over which the collection was made, and eleven a considered to be entirely new species. Twenty plates a included, containing a number of outline sketches for faci tating identification.

THE Anthropological Institute has issued an index to i publications. The index includes communications publish in the journal and transactions of the Ethnological Society fro 1843 to 1871; those in the journal and memoirs of the A thropological Society (1863-71), and also those that ha appeared in the *Anthropological Review*. In 1871 the Ethn logical and Anthropological Societies united to form the A thropological Institute, and since then all papers have appear in the Institute's journal. The first twenty volumes of t journal are included in the index.

Cosmos contains an article by M. C. Maze, from which appears that droughts such as we have experienced this ye follow a cycle of forty-two years. Since, however, the obser ations discussed have not been obtained from one place, a there is no clear definition as to what constitutes a dry seaso the theory can hardly be said to be above suspicion.

MESSRS. TAYLOR AND FRANCIS will shortly publish a wor by Griffith Brewer and Patrick Y. Alexander, on "Aëronautics being an abridgement of aëronautical specifications filed at t Patent Office between 1851 and 1891.

MESSRS. G. P. PUTMAN'S SONS have published for Dr. Lau Sodré, the Governor of Pará, Brazil, a work on "The State Pará." The work is in five parts, by different contributor dealing respectively with the history of Pará, physical feature public instruction, revenues and commerce, and industries.

THE *Journal of the Franklin Institute* for September contai among other things the continuation of Nikola Tesla's lectu "On Sight and other High Frequency Phenomena," and th conclusion of the lecture, by Dr. Richards, on "The Specif Heats of the Metals."

THE Calendar of the University College, Bristol, for the session 1893–94 has just been issued through Mr. Arrowsmith, of Bristol.

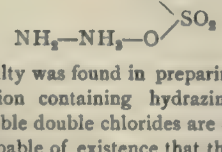
PROF. KINCH, of the Royal Agricultural College, Cirencester, has just issued a report of some of his field experiments for 1892 and 1893.

MR. W. F. STANLEY, of Great Turnstile, Holborn, has sent us the new edition of his catalogue of mathematical instruments made and sold by him. It is excellently printed upon good paper, and is very admirably classified.

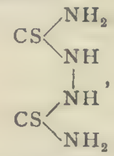
THE U.S. Department of Agriculture, division of Entomology, has lately brought out Vol. v., No. 5, of "Insect Life."

WE are informed by a correspondent that the Rev. L. Blomefield, whose death we recorded in last week's NATURE, was in his ninety-fourth year, and not, as stated by us, in his ninety-first.

FURTHER information concerning hydrazine, N_2H_4, and its compounds is contained in an inaugural dissertation by one of Prof. Curtius's assistants at Kiel, Herr Franz Schrader, and a brief account of it will be found in the current *Chemiker Zeitung*. A considerable time has now elapsed since the first preparation of hydrazine, which was announced by Prof. Curtius in June, 1887, and it is almost three years since full details were published concerning the isolation of the pure hydrate, a liquid of the composition $N_2H_4.H_2O$ which boils at 119°. It was then stated (vide NATURE, vol. 43, p. 205) that in closed vessels this hydrate may be preserved unaltered for any length of time. The experience of the last three years, however, necessitates a modification of that statement, and Herr Schrader now informs us that the liquid stored in sealed tubes decomposes sooner or later, the principal product of decomposition being ammonium hydrate. No gas appears to be generated during the process, so that tubes containing it do not become dangerous from accumulation of pressure. The reactions between the hydrate and a large number of metallic oxides are described, in which the strong reducing proclivities of hydrazine are very markedly exhibited, the reaction being frequently of an explosive character. Herr Schrader further describes a series of double sulphates containing hydrazine sulphate and the sulphate of a metal. Their general formula is $R''SO_4.(N_2H_4)_2H_2SO_4$ where R″ may represent copper, nickel, cobalt, iron, manganese, zinc and cadmium. These double sulphates, which contain no water of crystallisation, and are further distinguished from the double sulphates containing ammonium by their difficult solubility, are readily prepared by the admixture of solutions of the constituent simple sulphates. The constitution of the salts is probably expressed by the formula,



Considerable difficulty was found in preparing double chlorides of fixed composition containing hydrazine-chloride. Good crystals of very soluble double chlorides are easily obtained, but so many appear capable of existence that the conditions for the formation of salts of definite constitution have not yet been ascertained. Two entirely new compounds of hydrazine are described by Herr Schrader. By saturating hydrazine hydrate with sulphocyanic acid, or by decomposing hydrazine sulphate with barium sulphocyanate, hydrazine sulphocyanate, $N_2H_4.HSCN$, is obtained as a deliquescent solid substance which melts at 80°. When this hydrazine sulpho cyanate is heated, or when molecular proportions of hydrazine dichloride $N_2H_4\,2HCl$ and ammoniumsulpho cyanate in aqueous solution are heated for four or five hours in a sealed tube to 100°, a second new substance of urea-like constitution,



is formed. This second substance, hydrazine sulphocarbamide crystallises well from solution in hot water and melts at 214–215°. Its properties are somewhat remarkable, inasmuch as it appears to possess fairly strong acid properties, its solution yielding very characteristic precipitates with solutions of most metallic salts. The dissertation of Herr Schrader likewise reviews most of the work which has been carried out in the Kiel laboratories in connection with hydrazine, and adds many little details of importance in the practical manipulation of the substance and its compounds.

NOTES from the Marine Biological Station, Plymouth.—Last week's captures include the Actinian *Zoanthus Couchii* and the Archiannelid *Histriobdella Homari*. In the floating fauna *Noctiluca*, *Obelia* medusæ, Cirrhipede *Nauplii* and Caridid larvæ were plentiful; *Sagitta*, *Oikopleura* and the tubicolous larvæ of *Terebella* were fairly numerous. Specimens were also taken of the Leptomedusæ *Willia stellata* and *Eucopium quadratum*, of young stages of *Geryonia*, of *Doliolum Tritonis* and Ascidian larvæ, and of the larvæ of the Gephyrean *Thalassema*. The Nemertine *Amphiporus pulcher* and the Mollusc *Goniodoris castanea* are now breeding.

THE additions to the Zoological Society's Gardens during the past week include a Sooty Mangabey (*Cercocebus fuliginosus*, ♀) from West Africa, presented by Miss Grimston; two Brazilian Cariamas (*Cariama cristata*) from Brazil, presented by Mr. Lindsay C. Scott; a Melodious Jay Thrush (*Leucodioptron canorum*) from China, presented by Mr. B. H. Jones, F.Z.S.; a Wall Lizard (*Lacerta muralis* var. *taliguerta*) from Triest, presented by Mr. A. W. Arrowsmith; a Chilian Teal (*Querquedula creccoides*) from Antarctic America, a Little Tern (*Sterna hirundo*) from Brit. Isles, an Axis Deer (*Cervus axis*, ♂) from India, and a St. Thomas's Conure (*Conurus pertinax*) from West Indies, purchased.

OUR ASTRONOMICAL COLUMN.

MR. TEBBUTT'S OBSERVATORY.—We have received from Mr. Tebbutt the report of the work that has been done during the year 1892 at his observatory. In addition to meridian observations a great many extra-meridian observations were made, among which we may name the following:—Forty-five phases of occultations of stars by the moon, several observations of the phenomena of Jupiter's satellites, twenty good comparisons of the planet Mars, when in conjunction with Iota Aquarii, with that star, by means of the filar micrometer on the 8-inch equatorial, numerous observations of the comets visible in that year, about fifteen double-star measures and the variable star observations, including a few comparisons of η Argus and R. Carinæ with neighbouring stars. The meteorological observations have been regularly taken. Under the heading "Personal Establishment," an idea of the energy and zeal which Mr. Tebbutt shows for this science can be gathered from the fact that all the astronomical, and nearly all the meteorological observations are made by himself. Occasionally his son takes the meteorological readings during his absence from home, while the assistance of a computer is sometimes made use of. Although Mr. Tebbutt has received from several astronomers many suggestions as to work desirable to be done, he, nevertheless, wishes to fulfil the main work of the observatory, which consists in observations of lunar occultations of stars, southern comets, and the meteorological observations. That Mr. Tebbutt is thinking about seeking some relaxation, is only natural when one considers how his powers must have been taxed during the last few years; and we sincerely hope that after a good holiday and rest he may come back to his work again a new man, and continue the work he has so ably begun.

UNIVERSAL TIME IN AUSTRALIA.—With three meridians differing by one hour from one another passing through the continent of Australia, the question has been raised as to whether only central time should be used, or all three times. (*The Observatory* for September). Adopting the latter, it will be necessary, of course, for frequent changes of time to be made; but with the former, although places on the extreme east and west would have their time about 1½ hours away from local time, greater convenience for railways, telegraph work, &c., will be gained. Sir Charles Todd, who supports this latter view, and who is backed by the Hon. J. G. Ward (New Zealand), the Hon. J. Kidd (N.S.W.), and the Hon. A. Wynne (Victoria), came to the following conclusion at the Postal and Telegraph Conference held in Brisbane this year, when the subject of the Hour Zone Time was being considered:—"That it is desirable in the public interests that the Hour Zone system should be adopted in a modified form, so that there should be one time throughout Australia, viz. that of the 135th meridian, or nine hours east of Greenwich."

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 4.—M. Lœwy in the chair.—Report upon a memoir by M. Defforges, entitled, on the distribution of the intensity of gravity at the surface of the globe, by MM. Fizeau, Daubrée, Cornu, Bassot, Tisserand. This memoir, submitted to the judgment of the Academy by the Minister of War, summarises the theoretical and experimental researches made during eight years in the geographical service of the army, with the object of determining the absolute intensity of gravitation for a small number of primary stations, and the relative intensity for a large number of secondary stations with simplified apparatus. The latter were determined by means of the "reversible invertible pendulum" invented by M. Defforges, which exceeds all used previously in lightness and convenience, and easily gives an approximation to within 1 part in 100,000. The anomalies extending along a line from Spitzbergen through the Shetlands, Scotland, England, France, and Algiers considerably exceed any possible experimental errors, and the excess of gravitation on the islands and defect on the continents is well established. The report, which was adopted by the Academy, advises the Government to supply M. Defforges with the means to extend his work to the islands of the southern hemisphere and especially the Pacific.—The hypothesis of sub-continental bells, by M. Rateau. The phenomena of the earth's crust are well explained and connected by assuming that the crust underneath the continents does not touch the fluid globe, but is separated from it by a space filled with gaseous matter under pressure. The continents would thus form a sort of bells, very much flattened, and supported by gas, whereas the ocean beds would lie direct upon the igneous globe. The continental projections tend generally to rise, blown up as it were by the accumulating gas below, whilst the sea-beds sink. But the gases, imprisoned under high pressure, escape gradually through the fissures of the crust, when the production of new quantities from the nucleus will become insufficient, the pressure under the continents will decrease, and these will be projected upon the new crust underneath, giving rise to more or less extended crateriform configurations. This is the state in which we see the moon at the present time. If the earth's crust is assumed to be 30 km. thick, the pressure of the gases should be 650 atmospheres and their temperature 900°. The gases would be of a density nearly equal to that of water, and superposed in the order: hydrogen, methane, nitrogen, ethane, oxygen, carbonic anhydride. Hydrochloric acid and siliciuretted hydrogen would also probably be stable under these conditions. The presence of gas underneath the continents, elevated as they are above the sea and of greater density than water, is necessitated by conditions of hydrostatic equilibrium. It is easily seen why volcanoes in the interior of continents never give off larva, but only gases; also why lines of coast volcanoes have successively receded inland where the sea encroached.—On the elimination of foreign bodies in the *Acephala* and especially in *Pholas*, by M. Henri Coupin. If the mantle and the ventral siphon of the Pholas are cut along their entire length, and a collection of foreign particles are thrown upon the tentacles, the particles falling upon the dorsal tentacles are carried away with great rapidity, not towards the mouth, but upon that part of the mantle which lies between the anterior luminous organ and the palp. Thence they pass quickly towards the siphon region, and are stuck together by mucus and rolled up into balls, which are then extruded at the siphon. It is thus that the animal gets rid of the particles of rock disintegrated during its boring operations, and protects its delicate internal canals.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Index to the Publications of the Anthropological Institute (1843 to 1891): G. W. Bloxam (Anthropological Institute).—The Amphioxus and its Development: Dr. B. Hatschek, translated and edited by J. Tuckey (Sonnenschein).—The Pharmacopœia of the United States of America, 7th Decennial Revision, 1890 (Philadelphia).—London Inter. Science and Prelim. Sci. Directory, No. iv. July 1893 (London).—Accidents de Chaudières: F. Sinigaglia (Paris, Gauthier-Villars).—Théorie des Jeux de Hasard: H. Laurent (Paris, Gauthier-Villars).—Smithsonian Institution, Report of National Museum for Year ending June 30, 1891 (Washington).—An Elementary Text-book of Biology: J. R. A. Davis, 2nd edition, 2 parts (Griffin).—Publicazione della Specola Vaticana, fasc. iii. (Rome).—Bulletin of the U.S. Fish Commission, Vol. x. for 1890 (Washington).—Index Kewensis: Sir J. D. Hooker and B. D. Jackson. Part 1 (Oxford, Clarendon Press).—A Contribution to the Geology and Natural History of Nottinghamshire: edited by J. W. Carr (Nottingham, Bell).—Illustrated Hand-book of the Cape and South Africa: edited by J. Noble (Stanford).—Terra: A. A. Anderson, 2nd edition (Reeves and Turner).

PAMPHLETS.—Abstract of Returns furnished to the Department of Science and Art (Eyre and Spottiswoode).—Report of Mr. Tebbutt's Observatory, the Peninsula, Windsor, N.S.W. 1892: J. Tebbutt (Sydney).

SERIALS.—Journal of the Anthropological Institute, August (K. Paul).—Natural Science, September (Macmillan).—Geological Magazine, September (K. Paul).—American Journal of Mathematics, Vol. xv. No. 3 (Baltimore).—Journal of the Asiatic Society of Bengal, Vol. 62, Part 2, No. 1 (Calcutta).—Journal of the Chemical Society, September (Gurney and Jackson).—Proceedings of the American Philosophical Society, Vol. 31, No. 141 (Philadelphia).—Proceedings of the Rochester Academy of Science, Vol. 2, Brochure 2 (Rochester, New York).—Geological and Natural History Survey of Minnesota, Bulletin No. 8 (Minneapolis).—Medical Magazine, September (Southwood).—Proceedings of the Royal Society of Edinburgh, Session 1892–93, Vol. xx. pp. 1 to 96.—Journal of the College of Science, Imperial University, Japan, Vol. 6, Part 2 (Tokyo).

CONTENTS.

THURSDAY, SEPTEMBER 21, 1893.

THE BRITISH ASSOCIATION.

THE Nottingham meeting of the British Association must be recorded as a useful and pleasant one. There has been no tremendous sensation, but on the other hand there has not been much dulness. The weather up to Tuesday was everything that could be desired, and the proceedings were wound up yesterday by an innovation in the shape of a special performance of *Pharaoh* by Mr. Wilson Barrett and his company, to which the members of the Association were invited by the local committee.

The formal business of the Association was commenced on the 13th by a meeting of the general committee. From the council's report we cull the following announcements. The following were elected corresponding members:—Dr. Svante Arrhenius, Stockholm; Prof. Marcel Bertrand, Paris; Prof. F. Elfving, Helsingfors; Prof. Léo Errera, Brussels; Prof. G. Fritsch, Berlin; Mr. D. C. Gilman, Baltimore; Dr. C. E. Guillaume, Sèvres; Prof. Rosenthal, Erlangen; Dr. Maurits Snellen, Utrecht.

The council had drawn the attention of the Local Government Board to the desirability of the publication of the "Report on the Examination into Deviations from the Normal amongst 50,000 Children in various Schools," which had been presented to that board by the British Medical Association, and of several departments to the anthropometric method for the measurement of criminals, which is successfully in operation in France, Austria, and other continental countries.

At the meeting in the evening, in the Albert Hall, the retiring president, Sir A. Geikie, vacating the chair, spoke as follows:—Ladies and gentlemen, the last duty which your president for the year has to perform is to vacate the chair and formally introduce the new president. Allow me to thank you for the high honour of occupying the chair of the British Association, and at the same time to express the satisfaction with which I learn that the affairs of the British Association are in as satisfactory a condition as that in which I found them. The introduction of my successor is only a matter of form. His name is familiar to all of you, and he is esteemed all over the world as one of the great leaders of biological science—a great leader as well as a great investigator. He will speak to you with the authority of an acknowledged master of science. I have, therefore, great pleasure in introducing my successor in the chair, the Oxford professor, Dr. Burdon-Sanderson.

The President then delivered the address which we printed last week. Dr. Burdon-Sanderson's reference to the importance of the endowment of research has called forth remarks in the Press which clearly indicate that the people of this country do not yet see that in the peaceful war among nations that nation will win which has all the resources of science most easily at its command; that these resources are as much the first line of defence as the British Navy in actual war is our first line; and that with regard to them we are getting relatively worse equipped each year in consequence of the care with which science is being fostered by foreign governments and neglected by our own. We are in the same position to-day with regard to science as we were in the days of Queen Elizabeth with regard to the Navy.

The sectional meetings began next day. The addresses of the various presidents have shown a high level of excellence. This week we give those delivered in Sections C, D, G and H.

On Monday another meeting of the general committee was held in the afternoon for the purpose of determining upon the place of meeting in 1895. A deputation attended from Toronto, and Prof. Mavor, speaking on behalf of a local provisional committee, explained the facilities which Toronto afforded for the holding of general and sectional meetings. He also dwelt on the industries of the neighbourhood, its agriculture, and objects of scientific interest in the vicinity. It was eventually agreed that the committee express their best thanks to the provisional committee of Toronto for the invitation, and provided that suitable arrangements could be made similar to those that were made for the Montreal visit the committee would be prepared to entertain the question of meeting at Toronto before many years had elapsed.

Deputations were then introduced from Bournemouth and Ipswich. It appeared from information given by Mr. Griffith, the secretary, that Bournemouth offered greater facilities than Ipswich in the way of rooms for the meetings of the Sections. On the question being put to the vote, there appeared 31 for Ipswich and 20 for Bournemouth. It was, therefore, decided that the meeting of 1895 should be held at Ipswich.

The Marquis of Salisbury was nominated president of the meeting next year at Oxford. It was pointed out that among his claims he has been Chancellor of the University of Oxford since 1880, that he would therefore represent both hosts and guests, that he is a distinguished statesman, a courteous gentleman, a member of the council of the Royal Society, and a true man of science.

A list of vice-presidents was agreed to, and the meeting at Oxford was fixed for August 8.

The business concluded with the reappointment of Sir Douglas Galton and Mr. Vernon Harcourt as general secretaries, and Mr. G. Griffith as assistant general secretary, and Prof. Rücker as general treasurer.

The list of awards arrived at yesterday was as follows:

	£
Electrical Standards	25
Meteorological Photographs	10
Mathematical Tables	15
Solar Radiation	15
National Physical Laboratory	5
Wave-length Tables	10
Iron and Steel Analysis	15
Action of Light on Dyed Colours	5
Erratic Blocks	15
Fossil Phyllopoda	5
Geological Photographs	10
Shell-bearing Deposits at Clava, &c.	20
Eurypterids of the Pentland Hills	5
Sections of Stonesfield Slate	25
Earth Tremors	50
Exploration of Calf Hole Cave	5
Naples Zoological Station	100
Plymouth Zoological Station	15
Zoology of Sandwich Islands	100
Zoology of Irish Sea	40
Structure of Mammalian Heart	10
Climatology of Tropical Africa	10
Observations in South Georgia	50
Exploration in Arabia	30
Economic Training	10
Anthropometric Statistics	5
Ethnography of United Kingdom	10
The Glastonbury Village	40
Anthropometry in Schools	5
Mental and Physical Condition of Children ...	20
Corresponding Societies	25
	705

SECTION C.

GEOLOGY.

Opening Address by J. J. H. Teall, M.A., F.R.S., Sec.G.S., President of the Section.

It is a striking and remarkable fact that, although enormous progress has been made in petrographical science during the last hundred years, there has been comparatively little advance so far as broad, general theories relating to the origin of rocks are concerned. In Hutton's "Theory of the Earth," the outlines of which were published in 1788, the following operations are clearly recognised:—The degradation of the earth's surface by aqueous and atmospheric agencies; the deposition of the *débris* beneath the waters of the ocean; the consolidation and metamorphosis of the sedimentary deposits by the internal heat and by the injection of molten mineral matter; the disturbance and upheaval of the oceanic deposits; and, lastly, the formation of rocks by the consolidation of molten material both at the surface and in the interior of the earth.

Hutton regarded these operations as efficient causes ordained for the purpose of producing an earth adapted to sustain animal and vegetable life. His writings are saturated with the teleological philosophy of the age to which they belong, and some of his arguments strike us, therefore, as strange and inconclusive; moreover, the imperfect state of the sciences of chemistry and physics occasionally led him into serious error. Notwithstanding these imperfections, we are compelled to admit, when viewing his work in the light of modern knowledge, that we can find the traces, and sometimes far more than the traces, of those broad general theories relating to dynamical geology which are current at the present day.

If Hutton had contented himself with proving the reality of the agencies to which reference has been made it is probable that his views would have been generally accepted. But he went much further than this, and boldly maintained that one or other of these agencies, or several combined, would account for all the phenomena with which the geologist has to deal. It was this that gave rise to the controversial fire which blazed up with such fury during the early years of this century, and whose dying embers have not yet been extinguished.

The views of Hutton were in strong contrast to those of Werner, the celebrated professor of mineralogy at Freiberg, to whom science owes a debt of gratitude as great as that due to the Scottish physician. The value of a man's work must not simply be judged by the truth of the theory which he holds. I consider that the Wernerian theory—by which I understand a reference to the early stages of planetary evolution for the purpose of explaining certain geological facts—has been on the wane from the time it was propounded down to the present day; but I claim to be second to none in my admiration for the knowledge, genius, and enthusiasm of the illustrous Saxon professor. The uniformitarian doctrines of Hutton gave a very decided character to the theoretical views of British geologists during the middle of the century, in consequence of the eloquent support of Lyell; but of late there has been a tendency to hark back to a modified form of Wernerism. This tendency can, I think, be largely traced to the recognition of evolution as a factor in biology and physical astronomy. The discoveries in these sciences may necessitate a modification of the views held by some of the extreme advocates of uniformitarianism. This admission, however, by no means carries with it the conclusion that the methods based on the doctrine of uniformitarianism must be discarded. If I read the history of geology aright, every important advance in the theoretical interpretation of observed facts relating to physical geology has been made by the application of these methods. It does not, of course, follow that the progress in the future will be exactly along the same lines as that in the past; but, if I am right in the opinion I have expressed, it is a strong reason for adhering to the old methods until they have been proved to be inapplicable to at least some of the facts with which the physical geologist has to deal. Let us consider for a moment whether the recognition of evolution as a factor in biology and physical astronomy gives an *à priori* probability to some form of Wernerism.

The period of time represented by our fossiliferous records is perhaps equivalent to that occupied by the evolution of the vertebrata, but all the great subdivisions of the invertebrata were living in the Cambrian period, and must have been differentiated in still earlier times. Is it not probable, therefore, that the fossiliferous records at present known represent a period insignificant in comparison with that during which life has existed upon the earth? Again, is it not probable that the period during which life has existed is a still smaller fraction of that which has elapsed since the formation of the primitive crust? And if so, what *à priori* reason have we for believing that the rocks accessible to observation contain the records of the early stages of the planet's history? But the advocates of the diluted forms of Wernerism which find expression in geological writings at the present day almost invariably refer to recent speculations in cosmical physics. The views of astronomers have always had a powerful influence on those of geologists. Hutton wrote at a time when the astronomical world had been profoundly affected by Lagrange's discovery, in 1776, of the periodicity of the secular changes in the forms of the planetary orbits. The doubts as to the stability of the solar system which the recognition of these changes had inspired were thus removed, and astronomers could then see in the physical system of the universe "no vestige of a beginning,—no prospect of an end." Now it is otherwise. Tidal friction and the dissipation of energy by the earth and by the sun are each referred to as fixing a limit to the existing conditions. I have not the knowledge necessary to enable me to discuss these questions, and I will therefore admit, for the sake of argument, that the phenomena referred to indicate the lines along which the physical evolution of our planet has taken place; but does it follow that geologists should desert a working hypothesis which has led to brilliant results in the past for one which has been tried again and again and always found wanting?

If there were absolute unanimity amongst mathematical physicists, it might be necessary for us to reconsider our position. This, however, is not the case. After referring to the argument from tidal friction, Prof. Darwin, in his address to the Mathematical and Physical Section for 1886, says:—"On the whole, then, I can neither feel the cogency of the argument from tidal friction itself, nor, accepting it, can I place any reliance on the limits which it assigns to geological history." In reviewing the argument from the secular cooling of the earth, he points out that the possibility of the generation of heat in the interior by tidal friction has been ignored, and that the thermal data on which the calculations are based are not sufficiently complete to remove all reasonable doubt. He regards the case depending on the secular cooling of the sun as the strongest; but it is evident that, in view of undreamt-of possibilities, he would not allow it to have much weight in the face of adverse geological evidence. In conclusion he says:—"Although speculations as to the future course of science are usually of little avail, yet it seems as likely that meteorology and geology will pass the word of command to cosmical physics as the converse. At present our knowledge of a definite limit to geological time has so little precision that we should do wrong to summarily reject any theories which appear to demand longer periods of time than those which now appear allowable. In each branch of science hypothesis forms the nucleus for the aggregation of observation, and as long as facts are assimilated and co ordinated we ought to follow our theory." Now, my point is that the uniformitarian hypothesis, as applied to the rocks we can examine, has assimilated and coordinated so many facts in the past, and is assimilating and coordinating so many new discoveries, that we should continue to follow it, rather than plunge into the trackless waste of cosmogonical speculation in pursuit of what may after all prove to be a will-o'-the-wisp.

As an additional illustration of the want of agreement amongst mathematical physicists on questions relating to the earth, I may refer to certain papers by Mr. Chree.[1] This author maintains that the modern theory of elasticity points to the conclusion that if a spherical globe, composed of a nearly incompressible elastic solid of the size of the earth, were set rotating as the earth is rotating, it would take the form which the earth actually possesses. How is the question of the fixity of the earth's axis affected by Mr. Chree's researches, and by the recent observations which prove a simultaneous change of latitude, in opposite directions, in Europe and at Honolulu? If geological facts point to a shifting of the position of the axis, is there any dynamical reason why they should not receive due consideration? Geologists want as much freedom as possible. We do not object to any limitations which are necessary in the interest of science, and we cordially welcome, and as a matter

[1] C. Chree, "On Some Applications of Physics and Mathematics to Geology," *Phil. Mag.*, vol. xxxii. (1891), pp. 233, 342.

of fact are largely dependent upon, assistance from other departments of knowledge; but those who would help us should bear in mind that the problems we have still to solve are extremely difficult and complex, so that if certain avenues of thought are closed on insufficient grounds by arguments of the validity of which we are unable to judge, but which we are naturally disposed to take on trust, the difficulties of our task may be greatly augmented and the progress of science seriously retarded. So far as I can judge, there is no *à priori* reason why we should believe that any of the rocks we now see were formed during the earlier stages of planetary evolution. We are free to examine them in our own way, and to draw on the bank of time to any extent that may seem necessary.

For some years past the greater part of my time has been devoted to a study of the composition and structure of rocks, and it has occurred to me that I might, on the present occasion, give expression to my views on the question as to whether the present position of petrographical science necessitates any important modification in the theoretical views introduced by the uniformitarian geologists. Must we supplement the ideas of Hutton and Lyell by any reference to primordial conditions when we endeavour to realise the manner in which the rocks we can see and handle were produced? The question I propose to consider is not whether some of these rocks *may* have been formed under physical conditions different from those which now exist—life is too short to make a discussion of geological possibilities a profitable pursuit—but whether the present state of petrographical science renders uniformitarianism untenable as a working hypothesis; and, if so, to what extent. There is nothing original in what I am about to lay before you. All that I propose to do is to select from the numerous facts and more or less conflicting views, bearing on the question I have stated, a few of those which appear to me to be of considerable importance.

The sedimentary rocks contain the history of life upon the earth, and on this account, as well as on account of their extensive development at the surface, they have necessarily received an amount of attention which is out of all proportion to their importance as constituent portions of the planet. They are, after all, only skin deep. If they were totally removed from our globe its importance as a member of the solar system would not be appreciably diminished. The general laws governing the formation and deposition of these sediments have been fairly well understood for a long time. Hutton, as we have already seen, clearly realised that the land is always wasting away, and that the materials are accumulating on the beds of rivers, lakes, and seas. The chemical effects of denudation are mainly seen in the breaking up of certain silicates and the separation of their constituents into those which are soluble and those which are insoluble under surface conditions. The mechanical effects are seen in the disintegration of rocks, and this may, under certain circumstances, take place without the decomposition of their component minerals.[1] Quartz and the aluminous silicates, which enter largely into the composition of shales and clays, are two of the most important insoluble constituents. It must be remembered, however, that felspars often possess considerable powers of resistance, and rocks which contain them may be broken up without complete or anything like complete decomposition of these minerals. Orthoclase, microcline, and oligoclase are the varieties which most successfully resist decomposition; and, as a natural consequence, occur most abundantly in sedimentary deposits. It is commonly stated that when felspars are attacked the general effect is to reduce them to a fine powder, composed of a hydrated silicate of alumina, and to remove the alkalies, lime, and a portion of the silica. But, as Dr. Sterry Hunt has so frequently urged, the removal of alkalies is imperfect, for they are almost invariably present in argillaceous deposits. Three, four, and even five per cent., consisting mainly of potash, may frequently be found. This alkali appears to be present in micaceous minerals, which are often produced, as very minute scales, during the decomposition of felspars. White mica, whether formed in this way or as a product of igneous or metamorphic action, possesses great powers of resistance to the ordinary surface agencies of decomposition, and so may be used over and over again in the making of sedimentary deposits. Brown mica is also frequently separated from granite and other rocks, and deposited as a constituent of sediments; but it is far more liable

[1] J. W. Judd, "Deposits of the Nile Delta," *Proc. Royal Soc.*, vol. xxxix. (1886), p. 213.

to decomposition than the common white varieties, and its geological life is, therefore, comparatively short.[1] Small crystals and grains of zircon, rutile, ilmenite, cyanite, and tourmaline are nearly indestructible, and occur as accessory constituents in the finer-grained sandstones.[2] Garnet and staurolite also possess considerable powers of resistance, and are not unfrequently present in the same deposits. If we except the last two minerals and a few others, such as epidote, the silicates containing lime, iron, and magnesia are, as a rule, decomposed by surface agencies and the bases removed in solution; augite, enstatite, hornblende, and lime-felspars are extremely rare as constituents of ordinary sediments.

The insoluble constituents resulting from the waste of land surfaces are deposited as gravel, sand, and mud; the soluble constituents become separated as solid bodies by evaporation of the water in inland seas and lagoons, by chemical action, and by organic life. They are deposited as carbonates, sulphates, chlorides, and sometimes, as in the case of iron and manganese, as oxides. The soluble silica may be deposited in the opaline condition by the action of sponges, radiolaria, and diatoms, or as sinter.

The question that we have now to consider is whether there is any marked difference between ancient and modern sediments. One of the oldest deposits in the British Isles is the Torridon sandstone of the north-west of Scotland. The recent discovery of *Olenellus* high up in the stratified rocks which unconformably overlie this deposit has placed its pre-Cambrian age beyond all doubt. Now this formation is mainly composed of quartz and felspar, at least in its upper part, and the latter mineral is both abundant and very slightly altered. One is naturally tempted, at first sight, to associate the freshness of the felspar with the great age of the rock—to assume either that the sand was formed at a time when the chemical agents of decomposition did not act with the same force as now, or that they had not been in operation for a sufficient length of time to eliminate the felspar. A pure quartzose sand is probably never formed by the direct denudation of a granitic or gneissose area. The coarser sediments thus produced contain in most, if not in all, cases a considerable amount of felspar. But felspar is more liable to decomposition by percolating waters when it occurs as a constituent of grit than when present in the parent rock. Silica may thus be liberated in a soluble form, and subsequently deposited on the grains of quartz so as to give rise to secondary crystalline faces, and kaolin may be produced as beautiful six-sided tablets in the interstices of the grit. When the grit is in its turn denuded the felspar is still further reduced in amount, and a purer quartz-sand is formed. As the coarser detrital material is used over and over again, thus measuring different periods of time like the sand in an hour-glass, the felspar and other decomposable minerals are gradually eliminated. The occurrence of a large amount of fresh felspar in the Torridon sandstone might, I say, at first sight be thought to be due to the great age of the rock. Any tendency to accept a view of this kind is, however, at once checked when attention is paid to the pebbles in the coarser conglomeratic beds of the same deposit. These consist largely of quartzite—a rock formed by the consolidation of as pure a quartz-sand as any known to exist in the later formations. We are therefore led to the conclusion that the special features of the Torridon sandstone are not a function of time, but of the local conditions under which the rock was produced.

A similar conclusion may be reached by considering other types of sediment. When the stratified rocks of the different geological periods represented in any limited area are compared with each other certain marked differences may be observed, but the different types formed in any one area at different times can often be paralleled with the different types formed in different areas at the same time, and also with those now forming beneath the waters of rivers, lakes, and seas. Deep sea, shallow water, littoral and terrestrial deposits can be recognised in the formations belonging to many geological periods, from the most ancient to the most recent; and there is no evidence that any of our sedimentary rocks carry us back to a time when the physical conditions of the planet were materially different

from those which now exist. After reviewing all the evidence at my disposal, I must, however, admit that the coarser as well as the finer deposits of the earlier periods appear to be more complex in composition than those of the later. The grits of the Palæozoic formations, taken as a whole, contain more felspar than the sandstones of the Mesozoic and Tertiary formations, and the slates and shales of the former contain more alkalies than the clays of the latter. This statement will hold good for the British Isles, even when allowance is made for the enormous amount of volcanic material amongst the older rocks—a phenomenon which I hold to be of purely local significance—but I strongly suspect that it will not be found to apply universally. In any case, it is not of much importance from our present point of view. All geologists will admit that denudation and deposition were taking place in pre-Cambrian times, under chemical and physical conditions very similar to, if not identical with, those of the present day.

There is, however, one general consideration of more serious import. Additions to the total amount of detrital material are now being made by the decomposition of igneous rocks, and there is no doubt that this has been going on during the whole period of time represented by our stratified deposits. It follows, therefore, as a necessary consequence that strict uniformitarianism is untenable, unless we suppose that igneous magmas are formed by the melting of sediments.

So far we have been dealing with the characters of sedimentary rocks as seen in hand-specimens rather than with those which depend on their distribution over large areas. Thanks to Delesse ("Lithologie du Fond des Mers," Paris, 1871) and the officers of the *Challenger* Expedition ("Report on Deep-sea Deposits," 1891), an attempt has now been made to construct maps on which the distribution of the sediments in course of formation at the present time is laid down. It is impossible to exaggerate the importance of such maps from a geological point of view, for on the facts which they express rests the correct interpretation of our stratigraphical records. Imperfect as is our knowledge of the sea-beds of former geological periods, it is in many respects more complete than that of the sea-beds of the present day. The former we can often examine at our leisure, and follow from point to point in innumerable exposures; the latter are known only from a few soundings, often taken at great distances apart.[1] An examination of such imperfect maps as we have raises many questions of great interest and importance, to one of which I wish to direct special attention—not because it is new, but because it is often overlooked. The boundary lines separating the distinct types of deposit on these maps are not, of course, chronological lines. They do not separate sediments produced at different times, but different sediments simultaneously forming in different places. Now, the lines on our geological maps are usually drawn by tracing the boundary between two distinct lithological types, and, as a natural consequence, such lines will not always be chronological lines. It is only when the existing outcrop runs parallel with the margin of the original area of deposit that this is the fact. Consider the case of a subsiding area—or, to avoid theory, let us say an area in which the water-level rises relatively to the land—and, for the sake of illustration, let us suppose that the boundary separating the districts over which sand and mud are accumulating remains parallel to the old coast-line during the period of deposition. This line will follow the retreating coast, so that if, after the consolidation, emergence, and denudation of the deposits, the outcrop happens to be oblique to the old shore, then the line on the geological map separating clay and sand will not be of chronological value. That portion of it which lies nearer to the position of the vanished land will represent a later period than that which lies further away. If such organisms as ammonites leave their remains in the different deposits, and thus define different chronological horizons with approximate accuracy, the imperfection of the lithological boundary as a chronological horizon will become manifest. It is not that the geological map is wrong. Such maps have necessarily to be constructed with reference to economic considerations, and from this point of view the lithological boundaries are of paramount importance. They are, moreover, in many cases the only boundaries that can be actually traced.[2]

Starkie Gardner, "On the Relative Ages of the American and the English Cretaceous and Eocene Series," *Geol. Mag* (1884), p. 492.

The geological millennium will be near at hand when we can construct maps which shall represent the distribution of the different varieties of sediment for each of the different geological periods. All we can say at present is that increase of knowledge in this direction tends greatly to strengthen the uniformitarian hypothesis. We can see, for example, that during Triassic times marine conditions prevailed over a large part of what is now the great mountain-belt of the Euro-Asiatic continent, whilst littoral and terrestrial conditions existed in the north of Europe; and we can catch glimpses of the onward sweep of the sedimentary zones during the great Cretaceous transgression, culminating in the widespread deep-sea[1] conditions under which the chalk was deposited.

We turn now to the igneous rocks. It is no part of my purpose to treat in detail of the growth of knowledge from an historical point of view, and to attempt to allot to each observer the credit due to him; but there is one name that I desire to mention in this connection, because it is that of a man who clearly proved the essential identity of ancient and modern volcanic rocks by the application of precise petrographical methods at a time when there was a very general belief that the Tertiary and pre-Tertiary rocks were radically distinct. I need hardly say that I refer to Mr. Samuel Allport.[2] He wrote at a time when observers in this country had to prepare their own sections, and those who, like myself, have had the privilege of examining many of his slides scarcely know which to admire most—the skill and patience of which they are the evidence, or the conciseness and accuracy of his petrographical descriptions. His papers do not occupy a large number of pages, but they are based on an amount of observation which is truly surprising. The general conclusions at which he arrived as to the essential identity of ancient and modern igneous rocks are expressed with the utmost confidence, and one feels, after going over his material, that this confidence was thoroughly justified. It is curious now to note that the one British champion of the distinctness of the Tertiary and pre-Tertiary rocks pointed to the difference between the Antrim and Limerick traps. These traps differ in exactly the same way as do the corresponding Tertiary and pre-Tertiary continental rocks, with this important difference. On the Continent the ophitic structure is characteristic of the pre-Tertiary rocks, whereas in the north of Ireland it is a marked feature of those of Tertiary age. We see, therefore, that the arguments for the distinctness of the two sets of rocks derived from the two areas, based in both cases on perfectly accurate observations, neutralise each other, and the case hopelessly breaks down as regards the basalts and dolerites.

In this country it is now generally recognised that when allowance is made for alterations which are necessarily more marked in the earlier than in the later rocks, there is no important difference either in structure or composition between the rhyolites, andesites, and basalts of the Palæozoic and Tertiary periods. But identity of structure and composition may in this case be taken to imply identity as to the physical conditions under which the rocks were produced. We are thus led to picture in our minds long lines of volcanoes fringing the borders of Palæozoic continents and rising as islands in the Palæozoic seas. Then, as now, there issued from the craters of these volcanoes enormous masses of fragmental material, a large portion of which was blown to dust by the explosive escape of steam and other gases from the midst of molten rock; and then, as now, there issued from fissures on their flanks vast masses of lava which consolidated as rhyolite, andesite, and basalt. We may sum up the case as regards the volcanic rocks by saying that, so long as observations are confined to a limited area, doubts may arise as to the truth of the uniformitarian view, but these doubts gradually fade away as the area of observation is extended. There are still some outstanding difficulties, such as the apparent absence of leucite lavas amongst the Palæozoic formations; but as many similar difficulties have been overcome in the past, it is improbable that those which remain are of a very formidable character.

So far we have been referring to rocks formed at the surface of the earth under conditions similar to those now in operation. But there are others, such as granite, gneiss, and mica-schist,

[1] Theodor Fuchs, "Welche Ablagerungen haben wir als Tiefseebildungen zu betrachten?" *Neues Jahrbuch f. Miner.* &c. Beilage, Band II., p. 487.

which are obviously unlike any of the products of surface agencies. If these rocks are forming now, it must be beneath the surface. This point was clearly realised by Hutton. Granite was proved by him to be an igneous rock of subterranean origin. His conclusions as to the formation of the schists are expressed in a passage so remarkable when viewed in connection with what I regard as the tendency of modern research, that I make no apology for quoting it at length. "If, in examining our land, we shall find a mass of matter which had been evidently formed originally in the ordinary manner of stratification, but which is now extremely distorted in its structure, and displaced in its position—which is also extremely consolidated in its mass, and variously changed in its composition—which therefore has the marks of its original or marine composition extremely obliterated, and many subsequent veins of melted mineral matter interjected; we should then have reason to suppose that here were masses of matter which, though not different in their origin from those that are gradually deposited at the bottom of the ocean, have been more acted upon by subterranean heat and the expanding power, that is to say, have been changed in a greater degree by the operations of the mineral region. If this conclusion shall be thought reasonable, then here is an explanation of all the peculiar appearances of the Alpine schistus masses of our land, those parts which have been erroneously considered as primitive in the constitution of the earth ("Theory of the Earth," vol. i. p. 375). Surely it is not claiming too much for our author to say that we have there, sketched in broad outline, the theories of thermal and dynamic metamorphism which are attracting so much attention at the present day.

The hypogene origin of the normal plutonic rocks and their formation at different periods, even as late as the Tertiary, are facts which are now so generally recognised that we may leave these rocks without further comment and pass on to the consideration of the crystalline schists.

Everyone knows that the statement, "He who runs may read," is untrue when the stratigraphical interpretation of an intensely folded and faulted district is concerned. The complexity produced by the earth-movements in such regions can only be unravelled by detailed work after definite palæontological and lithological horizons have been established. But if the statement be untrue when applied to districts composed of ordinary stratified rocks, still less can it be true of regions of crystalline schist where the movements have often been much more intense; where the original characters of the rocks have been profoundly modified; and where all distinct traces of fossils have in most cases been obliterated. If detailed work like that of Prof. Lapworth at Dobb's Linn was required to solve the stratigraphical difficulties of the Southern Uplands, is it not probable that even more detailed work will be required to solve the structural problems of such a district as the Highlands of Scotland, where the earth-stresses, though somewhat similar, have operated with greater intensity, and where the injection of molten mineral matter has taken place more than once both on a large and on a small scale? With these few general remarks by way of introduction, I will now call attention to what appear to me to be the most promising lines of investigation in this department of geology.

The crystalline schists certainly do not form a natural group. Some are undoubtedly plutonic igneous rocks showing original fluxion; others are igneous rocks which have been deformed by earth-stresses subsequent to consolidation; others, again, are sedimentary rocks metamorphosed by dynamic and thermal agencies, and more or less injected with "molten mineral matter"; and lastly, some cannot be classified with certainty under any of these heads. So much being granted, it is obvious that we must deal with this petrographical complex by separating from it those rocks about the origin of which there can be no reasonable doubt. Until this separation has been effected, it is quite impossible to discuss with profit the question as to whether any portions of the primitive crust remain. In order to carry out this work it is necessary to establish some criterion by which the rocks of igneous may be separated from those of sedimentary origin. Such a criterion may, I think, be found, at any rate in many cases, by combining chemical with field evidence.[1] If associated rocks possess the composition of grits, sandstones, shales and limestones, and contain also traces of stratification, it seems perfectly justifiable to conclude that they must have been originally formed by processes of denudation and deposition. That we have such rocks in the Alps and in the Central Highlands of Scotland, to mention only two localities, will be admitted by all who are familiar with those regions. Again, if the associated rocks possess the composition of igneous products, it seems equally reasonable to conclude that they are of igneous origin. Such a series we find in the North-West of Scotland, in the Malvern Hills, and at the Lizard. In applying the test of chemical composition it is very necessary to remember that it must be based, not on a comparison of individual specimens, but of groups of specimens. A granite and an arkose, a granitic gneiss and a gneiss formed by the metamorphosis of a grit, may agree in chemical and even in mineralogical composition. The chemical test would therefore utterly fail if employed for the purpose of discriminating between these rocks. But when we introduce the principle of paragenesis it enables us in many cases to distinguish between them. The granitic gneiss will be associated with rocks having the composition of diorites, gabbros, and peridotites; the sedimentary gneiss with rocks answering to sandstones, shales, and limestones. Apply this test to the gneisses of Scotland, and I believe it will be found in many cases to furnish a solution of the problem. Caution, however, is necessary; for crystal-building and the formation of segregation veins and patches in the sedimentary schists clearly prove that a migration of constituents takes place under certain circumstances.

Recent work on the gneisses and schists of igneous composition has shown that the parallel structure, by no means invariably present, is sometimes the result of fluxion during the final stages of consolidation, and sometimes due to the plastic deformation of solid rocks. When compared with masses of ordinary plutonic rock, the principal points of difference, apart from those due to secondary dynamic causes, depend on what may be called their extreme petrographical differentiation. Indications of differentiation may, however, be seen in the contemporaneous veins and basic patches so common in ordinary irruptive bosses, but they are never so marked as in gneissic regions, like those of the North-West of Scotland, where specimens answering in composition to granites, diorites, and even peridotites, may be collected repeatedly in very limited areas. The nearest approach to the conditions of gneissose regions is to be found in connected masses of diverse plutonic rocks, such as those which are sometimes found on the borders of great granitic intrusions.

The tectonic relations of those gneisses which resemble igneous rocks in composition fully bear out the plutonic theory as to their origin. Thus, the intrusive character of granitic gneiss in a portion of the Himalayas has been demonstrated by General McMahon.[1] The protogine of Mont Blanc has been investigated by M. Lévy[2] with the same result. Most significant of all are the discoveries in the vast Archæan region of Canada. Professor Lawson[3] has shown that immense areas of the so-called Laurentian gneiss in the district north west of Lake Superior are intrusive in the surrounding rocks, and therefore newer, not older, than these. Professor Adams[4] has quite recently established a similar fact as regards the anorthosite rocks—the so-called Norian—of the Saguenay River and other districts lying near the eastern margin of the "Canadian shield." Now that the intrusive character of so many gneisses is being recognised, one wonders where the tide of discovery will stop. How long will it be before the existence of gneisses of Tertiary age will be generally admitted? At any rate, the discoveries of recent years have compelled the followers of Wernerian methods to evacuate large slices of territory.

Turning now to the gneisses and schists which resemble sedimentary rocks in composition, we note that the parallel structure may be due to original stratification, to subsequent deformation, or to both of these agencies combined. It must also be remembered that they have often been injected with igneous material, as Hutton pointed out. Where this has followed parallel planes of weakness, we have a banding due to alternations of igneous and sedimentary material. This injection

lit par lit has been shown by M. Lévy to be a potent cause in the formation of certain banded gneisses.

Will the various agencies to which reference has been made explain all the phenomena of the crystalline schists and gneisses? I do not think that the present state of our knowledge justifies us in answering this question in the affirmative. Those who are working on these rocks frequently have brought under their notice specimens about the origin of which they are not able to speak with any degree of confidence. Sometimes a flood of light is suddenly thrown on a group of doubtful rocks by the recognition of a character which gives unmistakable indications of their mode of origin. Thus, some of the fine-grained quartz-felspathic rocks associated with the crystalline schists of the Central Highlands are proved to have been originally sands like those of Hampstead Heath by the presence in them of narrow bands rich in zircon, rutile, and the other heavy minerals which are so constantly present in the finer-grained arenaceous deposits of all ages. Such pleasant surprises as the recognition of a character like this increase our confidence in the theory which endeavours to explain the past by reference to the present, and refuses to admit the necessity of believing in the existence of rocks formed under physical conditions different from those which now prevail simply because there are some whose origin is still involved in mystery.

A crystalline schist has been aptly compared to a palimpsest. Historical records of priceless value have often been obscured by the superposition of later writings; so it is with the records of the rocks. In the case of the schists, the original characters have been so modified by folding, faulting, deformation, crystallisation, and segregation that they have often become unrecognisable. But when the associated rocks have the composition of sediments we need have no hesitation in attributing the banded structure in some way to stratification, provided we clearly recognise that the order of succession and the relative thicknesses of the original beds cannot be ascertained by applying the principles which are valid in comparatively undisturbed regions.

In studying the crystalline schists nothing, perhaps, strikes one more forcibly than the evidence of crystal-building in solid rocks. Chiastolite, staurolite, andalusite, garnet, albite, cordierite, micas of various kinds, and many other minerals have clearly been developed without anything like fusion having taken place. Traces of previous movements may not unfrequently be found in the arrangement of the inclusions, while the minerals themselves show no signs of deformation. Facts of this kind, when they occur, clearly indicate that the crystallisation was subsequent to the mechanical action. Nevertheless, it is probable that both phenomena were closely related, though not in all cases as cause and effect. The intrusion of large masses of plutonic rock often marks the close of a period of folding. This is well illustrated by the relation of granite to the surrounding rocks in the Lake District, the Southern Uplands of Scotland, and the West of England. Those of the two first-mentioned localities are post-Silurian and pre-Carboniferous, those of the last-mentioned locality are post-Carboniferous and pre-Permian; one set followed the Caledonian[1] folding, the other set followed the Hercynian folding. That the intrusion of these granites was subsequent to the main movements which produced the folding and cleavage is proved by the fact that the mechanical structures may often be recognised in the crystalline contact-rocks, although the individual minerals have not been strained or broken. In many other respects the rocks produced by so-called contact-metamorphism resemble those found in certain areas of crystalline schist. Many of the most characteristic minerals are common to the two sets of rocks, and so also are many structures. The cipolins and associated rocks of schistose regions have many points of resemblance to the crystalline limestones and "kalksilicathornfels" produced by contact-metamophism.[2]

These facts make it highly probable that, by studying the metamorphic action surrounding plutonic masses, we may gain an insight into the causes which have produced the crystalline schists of sedimentary origin; just as, by studying the intrusive masses themselves and noting the tendency to petrographical differentiation, especially at the margins, we may gain an insight into the causes which have produced the gneisses of igneous origin.[1] In the districts to which reference has been made the igneous material came from below into a region where the rocks had been rendered tolerably rigid. Differential movement was not taking place in these rocks when the intrusion occurred. Consider what must happen if the folding stresses operate on the zone separating the sedimentary rocks from the underlying source of igneous material. Intrusion must then take place during interstitial movement, fluxion structures will be produced in the more or less differentiated igneous magmas, the sediments will be injected and impregnated with igneous material, and thermo-metamorphism will be produced on a regional scale. The origin of gneisses and schists, in my opinion, is to be sought for in a combination of the thermal and dynamic agencies which may be reasonably supposed to operate in the deeper zones of the earth's crust. If this view be correct it is not improbable that we may have crystalline schists and gneisses of post-Silurian age in the North-West of Europe formed during the Caledonian folding, others in Central Europe of post-Devonian age due to the Hercynian folding, and yet others in Southern Europe of post-Cretaceous age produced in connection with the Alpine folding.[3] But if the existence of such schists should ultimately be established it will still probably remain true that rocks of this character are in most cases of pre-Cambrian age. May not this be due to the fact, suggested by a consideration of the biological evidence, that the time covered by our fosisliferous records is but a small fraction of that during which the present physical conditions have remained practically constant?

The good old British ship "Uniformity," built by Hutton and refitted by Lyell, has won so many glorious victories in the past, and appears still to be in such excellent fighting trim, that I see no reason why she should haul down her colours either to "Catastrophe" or "Evolution." Instead, therefore, of acceding to the request to "hurry up" we make a demand for more time. The early stages of the planet's history may form a legitimate subject for the speculations of mathematical physicists, but there seems good reason to believe that they lie beyond the ken of those geologists who concern themselves only with the records of the rocks.

In this address I have ventured to express my views on certain disputed theoretical questions, and I must not conclude without a word of caution. The fact is, I attach very little importance to my own opinions, at least on doubtful questions connected with the origin of the crystalline schists; but, as you have done me the honour to accept me as your President, I thought you might like to know my present attitude of mind towards some of the unsolved problems of geology. There is still room for legitimate difference of opinion on many of the subjects to which I have referred. Meanwhile, we cannot do better than remember the words with which one of our great living masters recently concluded an article on a controversial subject: "Let us continue our work and remain friends."

[1] This term is employed in the sense in which it is used by Suess and Bertrand.

SECTION D.

BIOLOGY.

OPENING ADDRESS BY REV. H. B. TRISTRAM, M.A., LL.D., D.D., F.R.S., PRESIDENT OF THE SECTION.

IT is difficult for the mind to grasp the advance in biological science (I use the term biology in its wide etymological, not its recently restricted sense) which has taken place since I first attended the meetings of the British Association, some forty years ago. In those days, the now familiar expressions of

[1] G. Barrow, "On an Intrusion of Muscovite-biotite-gneiss in the South Eastern Highlands of Scotland, &c." *Quart. Journ. Geol. Soc.*, vol. xlix. (1893), p. 330.

[2] Some geologists maintain that this is the case, others deny it. See H. Reusch, "Die fossilienführenden krystallinischen Schiefer von Bergen in. Norwegen," Leipzig (1883) J. Lehmann, "Uber die Entstehung der altkrystallinischen Schiefergesteine, mit besonderer Bezugnahme auf des sächsische Granulitgebirge, Erzgebirge, Fichtelgebirge, und bairisch-böhmische Grenzgebirge," Bonn, (1884): T. G. Bonney. several papers on the Alps, and especially "On the Crystalline Schists and their Relation to the Mesozoic Rocks of the Lepontine Alps," *Quart. Journ. Geol Soc.*, vol. xlvi. (1890), p. 188; A. Heim, contribution to the discussion on the last paper; C. W. Gümbel, "Geognostische Beschreibung des K. Bayern" and "Grundzüge der Geologie," Kassel (1888-1892).

Although it is convenient to speak of the three types of folding which have so largely influenced the structure of the European continent as if each belonged to a definite period, it is important to remember that this is not strictly true. The movements were prolonged; they probably crept slowly over the surface of the lithosphere, as did the zones of sedimentation, so that those of the same type are not in all places strictly contemporaneous.

"natural selection," "isolation," "the struggle for existence," "the survival of the fittest," were unheard of and unknown, though many an observer was busied in culling the facts which were being poured into the lap of the philosopher who should mould the first great epoch in natural science since the days of Linnæus.

It is to the importance and value of field observation that I would venture in the first place to direct your attention.

My predecessors in this chair have been, of recent years, distinguished men who have searched deeply into the abstrusest mysteries of physiology. Thither I do not presume to follow them. I rather come before you as a survivor of the old-world naturalist, as one whose researches have been, not in the laboratory or with the microscope, but on the wide desert, the mountain side, and the isles of the sea.

This year is the centenary of the death of Gilbert White, whom we may look upon as the father of field naturalists. It is true that Sir T. Browne, Willughby, and Ray had each, in the middle of the seventeenth century, committed various observations to print; but though Willughby, at least, recognised the importance of the soft parts in affording a key to classification, as well as the osteology, as may be seen from his observation of the peculiar formations, in the Divers (*Colymbidæ*) of the tibia, with its prolonged procnemial process, of which he has given a figure, or his description of the elongation of the posterior branches of the woodpecker's tongue, as well as by his careful description of the intestines of all specimens which came under his notice in the flesh, none of these systematically noted the habits of birds, apart from an occasional mention of their nidification, and very rarely do they even describe the eggs. But White was the first observer to recognise how much may be learnt from the life habits of birds. He is generally content with recording his observations, leaving to others to speculate. Fond of Virgilian quotations (he was a fellow of Oriel of the last century), his quotations are often made with a view to prove the scrupulous accuracy of the Roman poet, as tested by his (White's) own observations.

In an age, incredulous as to that which appears to break the uniformity of nature, but quick to recognise all the phenomena of life, a contrast arises before the mind's eye between the abiding strength of the objective method, which brings Gilbert White in touch with the great writers whose works are for all time, and the transient feebleness of the modern introspective philosophies, vexed with the problems of psychology. The modern psychologist propounds his theory of man and the universe, and we read him, and go on our way, and straightway forget. Herodotus and Thucydides tell a plain tale in plain language, or the Curate of Selborne shows us the hawk on the wing, or the snake in the grass, as he saw them day by day, and, somehow, the simple story lives and moves him who reads it long after the subtleties of this or that philosophical theory have had their day and passed into the limbo of oblivion. But, invaluable as has been the example of Gilbert White in teaching us how to observe, his field was a very narrow one, circumscribed for the most part by the boundaries of a single parish, and on the subject of geographical distribution (as we know it now) he could contribute nothing, a subject on which even the best explorers of that day were strangely inobservant and inexact. A century and a half ago, it had not come to be recognised that distribution is, along, of course, with morphology and physiology, a most important factor in determining the facts of biology. It is difficult to estimate what might have been gained in the case of many species, now irreparably lost, had Forster and the other companions of Captain Cook, to say nothing of many previous voyagers, had the slightest conception of the importance of noting the exact locality of each specimen they collected. They seem scarcely to have recognised the specific distinctions of the characteristic genera of the Pacific Islands at all, or if they did, to have dismissed them with the remark, "On this island was found a flycatcher, a pigeon, or a parrot similar to those found in New Holland, but with white tail-feathers instead of black, an orange instead of a scarlet breast, or red shoulders instead of yellow." As we turn over the pages of Latham or Shaw, how often do we find for locality one of the islands of the South Sea, and, even where the locality is given, subsequent research has proved it erroneous, as though the specimens had been subsequently ticketed; Le Vaillant described many of his South African birds from memory. Thus Latham, after describing very accurately *Rhipidura flabellifera*, from the south island of New Zealand, remarks, apparently on Forster's authority, that it is subject to variation; that in the island of Tanna another was met with, with a different tail, &c., and that there was another variety in the collection of Sir Joseph Banks. Endless perplexity has been caused by the *Psittacus pygmæus* of Gmelin (of which Latham's type is at Vienna) being stated in the inventory as from Botany Bay, by Latham from Otaheite, and in his book as inhabiting several of the islands of the South Seas, and now it proves to be the female *Psittacus palmarum* from the New Hebrides. These are but samples of the confusion caused by the inaccuracies of the old voyagers. Had there been in the first crew who landed on the island of Bourbon, I will not say a naturalist, but even a simple-hearted Leguat, to tell the artless tale of what he saw, or had there been among the Portuguese discoverers of Mauritius one who could note and describe the habits of its birds with the accuracy with which a Poulton could record the ways and doings of our Lepidoptera, how vastly would our knowledge of a perished fauna have been enriched! It is only since we learned from Darwin and Wallace the power of isolation in the differentiation of species, that special attention has been paid to the peculiarities of insular forms. Here the field naturalist comes in as the helpful servant of the philosopher and the systematist, by illustrating the operation of isolation in the differentiation of species. I may take the typical examples of two groups of oceanic islands, differing as widely as possible in their position on the globe, the Sandwich Islands in the centre of the Pacific, thousands of miles from the nearest continent, and the Canaries, within sight of the African coast; but agreeing in this, that both are truly oceanic groups, of purely volcanic origin, the ocean depths close to the Canaries, and between the different islands, varying from 1500 to 2000 fathoms. In the one we may study the expiring relics of an avifauna completely differentiated by isolation; in the other we have the opportunity of tracing the incipient stages of the same process.

The Sandwich Islands have long been known as possessing an avifauna not surpassed in interesting peculiarity by that of New Zealand or Madagascar; in fact, it seems as though their vast distance from the continent had intensified the influences of isolation. There is scarcely a passerine bird in its indigenous fauna which can be referred to any genus known elsewhere. But, until the very recent researches of Mr. Scott Wilson, and the explorations of the Hon. W. Rothschild's collectors, it was not known that almost every island of the group possessed one or more representatives of each of these peculiar genera. Thus, every island which has been thoroughly explored, and in which any extent of the primeval forest remains, possesses, or has possessed, its own peculiar species of *Hemignathus*, *Himatione*, *Phæornis*, *Acrulocercus*, *Loxops*, *Drepanis*, as well as of the massive-beaked finches, which emulate the *Geospiza* of the Galapagos. Prof. Newton has shown that while the greater number of these are probably of American origin, yet the South Pacific has contributed its quota to this museum of ornithological rarities, which Mr. Clarke very justly proposes to make a distinct biological sub-region.

That each of the islands of this group, however small, should possess a flora specifically distinct, suggests thoughts of the vast periods occupied in their differentiation.

In the Canary Islands, either because they are geologically more recent, or because of their proximity to the African coast, which has facilitated frequent immigrations from the continent, the process of differentiation is only partially accomplished. Yet there is scarcely a resident species which is not more or less modified, and this modification is yet further advanced in the westernmost islands than in those nearest to Africa. In Fuertaventura and Lanzarote, waterless and treeless, there is little change, and the fauna is almost identical with that of the neighbouring Sahara. There is a whin-chat, *Pratincola dacotiæ*, discovered by my companion, Mr. Meade-Waldo, peculiar to Fuertaventura, which may possibly be found on the opposite coast, though it has not yet been met with by any collectors there. Now, our whin-chat is a common winter visitant all down the West African coast, and it seems probable that isolation has produced the very marked characters of the Canaries form, while the continental individuals have been restrained from variation by their frequent association with their migratory relations. A similar cause may explain why the blackbird, an extremely common resident in all the Canary Islands, has not been modified in the least, since many migratory individuals of the same species sojourn every winter in the islands. Or take the blue titmouse. Our familiar resident is replaced along the coast of North Africa by a representative species, *Parus ultramarinus*, differentiated chiefly by a black instead of a blue cap, and a slate-coloured instead of a green back. The titmouse of Lanzarote and Fuertaventura is barely separable from that of Algeria, but is much smaller and paler, probably owing to scarcity of food and a dry desert climate. Passing, 100 miles further to sea, to Grand Canary, we find in the woods and forests a bird in all respects similar to the Algerian in colour and dimensions, with one exception—the greater wing coverts of the Algerian are tipped with white, forming a broad bar when the wing is closed. This, present in the Fuertaventura form, is represented in the Canarian by the faintest white tips, and in the birds from the next islands, Tenerife and Gomera, this is altogether absent. This form has been recognised as *Parus teneriffæ*. Proceeding to the north-west outermost island, Palma, we find a very distinct species, with different proportions, a longer tail, and white abdomen instead of yellow. In the Ultima Thule, Hierro, we find a second very distinct species, resembling that of Tenerife in the absence of the wing bar and in all other respects, except that the back is green like the European, instead of slate as in all the other species. Thus we find in this group a uniform graduation of variation as we proceed further from the cradle of the race.

A similar series of modifications may be traced in the chaffinch (*Fringilla*), which has been in like manner derived from the North African *F. spodiogena*, and in which the extreme variation is to be found in the westernmost islands of Palma and Hierro. The willow wren (*Phylloscopus trochilus*), extremely numerous and *resident*, has entirely changed its habits, though not its plumage, and I have felt justified in distinguishing it as *Ph. fortunatus*. In note and habits it is entirely different from our bird, and though it builds a domed nest it is always near the top of lofty trees, most frequently in palm-trees. The only external difference from our bird consists in its paler tarsi and more rounded wing, so that its power of flight is weaker. but, were it not for the marked difference in its habits and voice, I should have hesitated to differentiate it. In the kestrel and the great spotted woodpecker there are differences which suggest incipient species, while the forests of the wooded western islands yield two very peculiar pigeons, differing entirely from each other in their habits, both probably derived from our wood-pigeon, but even further removed from it than the *Columba trocaz* of Madeira, and, by their dark chestnut coloration, suggesting that peculiar food, in this case the berries of the tree laurel, has its full share in the differentiation of isolated forms. If we remember the variability of the pigments in the food of birds, and the amount absorbed and transferred to the skin and plumage, the variability in the tints and patterns of many animals can be more readily understood.

One other bird deserves notice, the *Caccabis*, or red-legged partridge, for here, and here alone, we have chronological data. The Spaniards introduced *Caccabis rufa* into Canary, and *C. petrosa* into Tenerife and Gomera, and they have never spread from their respective localities. Now, both species, after a residence of only 400 years, have become distinctly modified. *C. rufa* was introduced into the Azores also, and changed exactly in the same manner, so much so that Mr. Godman, some years ago, would have described it as distinct, but that the only specimen he procured was in moult and mutilated, and his specimen proved identical with the Canarian bird. Besides minor differences, the back is one-fourth stouter and longer than in the European bird, and the tarsus very much stouter and longer, and the back is gray rather than russet. The gray back harmonises with the volcanic dark soil of the rocks of the Canaries, as the russet does with the clay of the plains of England and France. In the Canaries the bird lives under different conditions from those of Europe. It is on the mountain sides and among rocks that the stouter beak and stronger legs are indispensable to its vigorous existence. It is needless to go into the details of many other species. We have here the effect of changed conditions of life in 400 years. What may they not have been in 400 centuries? We have the result of peculiar food in the pigeons, and of isolation in all the cases I have mentioned. Such facts can only be supplied to the generaliser and the systematist through the accurate and minute observations of the field naturalist.

The character of the avifauna of the Comoro Islands, to take another insular group, seems to stand midway in the differentiating process between the Canaries and the Sandwich Islands. From the researches of M. Humblot, worked out by MM. Milne-Edwards and Oustalet, we find that there are twenty-nine species acknowledged as peculiar; two species from South Africa and twenty-two from Madagascar in process of specification, called by M. Milne-Edwards secondary or derived species.

The little Christmas Island, an isolated rock 200 miles south of Java, only 12 miles in length, has been shown by Mr. Lister to produce distinct and peculiar forms of every class of life, vegetable and animal. Though the species are few in number, yet every mammal and land bird is endemic; but, as Darwin remarks, to ascertain whether a small isolated area, or a large open area like a continent, has been more favourable for the production of new organic forms, we ought to make the comparison between equal times, and this we are incapable of doing. My own attention was first directed to this subject when, in the year 1857–58, I spent many months in the Algerian Sahara, and noticed the remarkable variations in different groups, according to elevation from the sea, and the difference of soil and vegetation. The "Origin of Species" had not then appeared; but on my return my attention was called to the communication of Darwin and Wallace to the Linnean Society on the tendencies of species to form varieties, and on the perpetuation of varieties and species by means of natural selection. I then wrote (*Ibis* 1859, pp. 429–433): "It is hardly possible, I should think, to illustrate this theory better than by the larks and chats of North Africa. In all these, in the congeners of the wheatear, of the rock chat, of the crested lark, we trace gradual modifications of coloration and of anatomical structure, deflecting by very gentle gradations from the ordinary type, but, when we take the extremes, presenting the most marked differences. . . . In the desert, where neither trees, brushwood, nor even undulations of surface afford the slightest protection to an animal from its foes, a modification of colour, which shall be assimilated to that of the surrounding country, is absolutely necessary. Hence, without exception, the upper plumage of every bird—whether lark, chat, sylvan or land grouse—and also the fur of all the small mammals, and the skin of all the snakes and lizards, is of the uniform isabelline or sand-colour. It is very possible that some further purpose may be served by the prevailing colours, but this appears of itself a sufficient explanation. There are individual varieties of depth of hue among all creatures. In the struggle for life which we know to be going on among all species, a very slight change for the better, such as improved means of escape from its natural enemies (which would be the effect of an alteration from a conspicuous colour to one resembling the hue of the surrounding objects), would give the variety that possessed it a decided advantage over the typical or other forms of the species. . . . To apply the theory to the case of the Sahara. If the Algerian Desert were colonised by a few pairs of crested larks—putting aside the ascertained fact of the tendency of an arid, hot climate to bleach all dark colours—we know that the probability is that one or two pairs would be likely to be of a darker complexion than the others. These, and such of their offspring as most resembled them, would become more liable to capture by their natural enemies, hawks and carnivorous beasts. The lighter-coloured ones would enjoy more or less immunity from such attacks. Let this state of things continue for a few hundred years and the dark-coloured individuals would be exterminated, the light-coloured remain and inherit the land. This process, aided by the above-mentioned tendency of the climate to bleach the coloration still more, would in a few centuries produce the *Galerida abyssinica* as the typical form; and it must be noted that between it and the European *G. cristata* there is no distinction but that of colour.

"But when we turn to *Galerida isabellina*, *G. arenicola*, and *G. macrorhyncha*, we have differences, not only of colour, but of structure. These differences are most marked in the form of the bill. Now, to take the two former first, *G. arenicola* has a very long bill, *G. isabellina* a very short one; the former resorts exclusively to the deep, loose, sandy tracts, the latter haunts the hard and rocky districts. It is manifest that a bird whose food has to be sought for in deep sand derives a great advantage from any elongation, however slight, of its bill. The other, who feeds among stones and rocks, requires strength rather than length. We know that even in the type species the size of the bill varies in individuals—in the lark as well as in the snipe. Now, in the desert, the shorter-billed varieties would undergo comparative difficulty in finding food where it was not abundant, and consequently would not be in such vigorous condition as their longer-billed relations. In the breeding season, therefore, they would have fewer eggs and a weaker progeny. Often, as we know, a weakly bird will abstain from matrimony altogether. The natural result of these causes would be that in course of time the longest-billed variety would steadily predominate over the shorter, and, in a few centuries, they would be the sole existing race; their shorter-billed fellows dying out until that race was extinct. The converse will still hold good of the stout-billed and weaker billed varieties in a rocky district.

"Here are only two causes enumerated which might serve to create, as it were, a new species from an old one. Yet they are perfectly natural causes, and such as I think must have occurred, and are possibly occurring still. We know so very little of the causes which, in the majority of cases, make species rare or common that there may be hundreds of others at work, some even more powerful than these, which go to perpetuate and eliminate certain forms 'according to natural means of selection.'"

It would appear that those species in continental areas are equally liable to variation with those which are isolated in limited areas, yet that there are many counteracting influences which operate to check this tendency. It is often assumed, where we find closely allied species apparently inter-breeding at the centre of their area, that the blending of forms is caused by the two races commingling. Judging from insular experience I should be inclined to believe that the theory of inter-breeding is beginning at the wrong end, but rather that while the generalised forms remain in the centre of distribution, we find the more decidedly distinct species at the extremes of the range, caused not by inter-breeding, but by differentiation. To illustrate this by the group of the blue titmouse. We find in Central Russia, in the centre of distribution of the family, the most generalised form, *Parus pleskii*, partaking of the characters of the various species east, west, and south. In the north-east and north it becomes differentiated as *P. cyaneus*; to the south-west and south into *P. cæruleus* and its various sub-species, while a branch extending due east has assumed the form of *P. flavipectus*, bearing traces of affinity to its neighbour *P. cyaneus* in the north, which seems evidently to have been derived from it.

But the scope of field observation does not cease with geographical distribution and modification of form. The closet systematist is very apt to overlook or to take no count of habits, voice, modification, and other features of life which have an important bearing on the modification of species. To take one instance, the short-toed lark (*Calandrella brachydactyla*) is spread over the countries bordering on the Mediterranean; but, along with it, in Andalusia alone is found another species, *Cal. bætida*, of a rather darker colour, and with the secondaries generally somewhat shorter. Without further knowledge than that obtained from a comparison of skins, it might be put down as an accidental variety. But the field naturalist soon recognises it as a most distinct species. It has a different voice, a differently-shaped nest; and, while the common species breeds in the plains, this one always resorts to the hills. The Spanish shepherds on the spot recognise their distinctness, and have a name for each species. Take, again, the eastern form of the common song-thrush. The bird of North China, *Turdus auritus*, closely resembles our familiar species, but is slightly larger, and there is a minute difference in the wing formula. But the field naturalist has ascertained that it lays eggs like those of the missel-thrush, and it is the only species closely allied to our bird which does not lay eggs of a blue ground colour. The hedge accentor of Japan (*Accentor rubidus*) is distinguished from our most familiar friend, *Accentor modularis*, by delicate differences of hue. But, though in gait and manner it closely resembles it, I was surprised to find the Japanese bird strikingly distinct in habits and life, being found only in forest and brushwood several thousand feet above the sea. I met with it first at Chinsenze—6000 feet—before the snow had left the ground, and in summer it goes higher still, but never descends to the cultivated land. If both species are derived, as seems probable, from *Accentor immaculatus* of the Himalayas, then the contrast in habits is easily explained. The lofty mountain ranges of Japan have enabled the settlers there to retain their original habits, for which our humbler elevations have afforded no scope.

On the solution of the problem of the migration of birds, the most remarkable of all the phenomena of animal life, much less aid has been contributed by the observations of field naturalists than might reasonably have been expected. The facts of migration have, of course, been recognised from the earliest times, and have afforded a theme for Hebrew and Greek poets 3000 years ago. Theories which would explain it are rife enough, but it is only of late years that any systematic effort has been made to classify and summarise the thousands of data and notes which are needed in order to draw any satisfactory conclusion. The observable facts may be classified as to their bearing on the whither, when, and how, of migration, and after this we may possibly arrive at a true answer to the Why? Observation has sufficiently answered the first question, Whither?

There are scarcely any feathered denizens of earth or sea to the summer and winter ranges of which we cannot now point. Of almost all the birds of the holo-arctic fauna, we have ascertained the breeding-places and the winter resorts. Now that the knot and the sanderling have been successfully pursued even to Grinnell Land, there remains but the curlew sandpiper (*Tringa subarquata*), of all the known European birds, whose breeding ground is a virgin soil, to be trodden, let us hope, in a successful exploration by Nansen, on one side or other of the North Pole. Equally clearly ascertained are the winter quarters of all the migrants. The most casual observer cannot fail to notice in any part of Africa, north or south, west coast or interior, the myriads of familiar species which winter there. As to the time of migration, the earliest notes of field naturalists have been the records of the dates of arrival of the feathered visitors. We possess them for some localities, as for Norfolk by the Marsham family, so far back as 1736. In recent years these observations have been carried out on a larger and more systematic scale by Middendorff, who, forty years ago, devoted himself to the study of the lines of migration in the Russian Empire, tracing what he called the *isopipteses*, the lines of simultaneous arrival of particular species, and by Prof. Palmén, of Finland, who, twenty years later, pursued a similar course of investigation; and by Prof. Baird on the migration of North American birds; and subsequently by Severtzoff as regards Central Asia, and Menzbier as regards Eastern Europe. As respects our own coasts, a vast mass of statistics has been collected by the labours of the Migration Committee appointed by the British Association in 1880, for which our thanks are due to the indefatigable zeal of Mr. John Cordeaux and his colleague Mr. John Harvie Brown, the originators of the scheme by which the lighthouses were for nine years used as posts of observation on migration. The reports of that committee are familiar to us, but the inferences are not yet worked out. I cannot but regret that the committee has been allowed to drop. Prof. W. W. Cooke has been carrying on similar observations in the Mississippi valley, and others, too numerous to mention, have done the same elsewhere. But, as Prof. Newton has truly said, all these efforts may be said to pale before the stupendous amount of information amassed during more than fifty years by the venerable Herr Gätke, of Heligoland, whose work we earnestly desire may soon appear in an English version.

We have, through the labours of the writers I have named, and many others, arrived at a fair knowledge of the When? of migration. Of the How? we have ascertained a little, but very little. The lines of migration vary widely in different species, and in different longitudes. The theory of migration being directed towards the magnetic pole, first started by Middendorff, seems to be refuted by Baird, who has shown that in North America the theory will not hold. Yet, in some instances, there is evidently a converging tendency in northward migrations. The line, according to Middendorff, in Middle Siberia is due north, in Eastern Siberia south-east to north-west, and in Western Siberia from south-west to north-east. In European Russia Menzbier traces four northward routes: (1) A coast line coming up from Norway round the North Cape to Nova Zembla. (2) The Baltic line with bifurcation, one proceeding by the Gulf of Bothnia, and the other by the Gulf of Finland, which is afterwards again subdivided. (3) A Black Sea line, reaching nearly as far north as the valley of the Petchora; and (4) the Caspian line, passing up the Volga, and reaching as far east as the valley of the Obi by other anastomosing streams.

Palmén has endeavoured to trace the lines of migration on the return autumnal journey in the eastern hemisphere, and has arranged them in nine routes: (1) From Nova Zembla, round the West of Norway, to the British Isles. (2) From Spitzbergen, by Norway, to Britain, France, Portugal, and West Africa. (3) From North Russia, by the Gulf of Finland, Holstein, and Holland, and then bifurcating to the West Coast of France on the one side, and on the other up the Rhine to Italy and North

Africa. (4*a*) Down the Volga by the Sea of Azof, Asia Minor, and Egypt, while the other portion (4*b*), trending east, passes by the Caspian and Tigris to the Persian Gulf. (5) By the Yenesei to Lake Baikal and Mongolia. (6) By the Lena on to the Amoor and Japan. (7) From East Siberia to the Corea and Japan. (8) Kamschatka to Japan and the Chinese coast. (9) From Greenland, Iceland, and the Farohs, to Britain, where it joins line 2.

All courses of rivers of importance form minor routes, and consideration of these lines of migration might serve to explain the fact of North American stragglers, the waifs and strays which have fallen in with great flights of the regular migrants and been more frequently shot on the east coast of England and Scotland than on the west coast or in Ireland. They have not crossed the Atlantic, but have come from the far north, where a very slight deflection east or west might alter their whole course, and in that case they would naturally strike either Iceland or the west coast of Norway, and in either case would reach the east coast of Britain. But, if by storms, and the prevailing winds of the North Atlantic coming from the west, they had been driven out of their usual course, they would strike the coast of Norway, and so find their way hither in the company of their congeners.

As to the elevation at which migratory flights are carried on, Herr Gätke, as well as many American observers, holds that it is generally far above our ken, at least in normal conditions of the atmosphere, and that the opportunities of observation, apart from seasons and unusual atmospheric disturbance, are confined chiefly to unsuccessful and abortive attempts. It is maintained that the height of flight is some 1500 to 15,000 feet, and if this be so, as there seems every reason to admit, the aid of land bridges and river valleys becomes of very slight importance. A trivial instance will illustrate this. There are two species of blue-throat, *Cyanecula suecica* and *C. leucocyana*: the former with its red-breast patch is abundant in Sweden in summer, but is never found in Germany, except most accidentally, as the other is the common form of Central Europe. Yet both are abundant in Egypt and Syria, where they winter, and I have on several occasions obtained both species out of the same flock. Hence we infer that the Swedish bird makes its journey from its winter quarters with scarcely a halt, while the other proceeds leisurely to its nearer summer quarters. On the other hand, I have more than once seen myriads of swallows, martins, sand-martins, and, later in the season, swifts, passing up the Jordan Valley and along the Bukoa of Central Syria, at so slight an elevation that I was able to distinguish at once that the flight consisted of swallows or house-martins. This was in perfectly calm clear weather. One stream of swallows, certainly not less than a quarter of a mile wide, occupied more than half an hour in passing over one spot, and flights of house-martins, and then of sand-martins, the next day, were scarcely less numerous. These flights must have been straight up from the Red Sea, and may have been the general assembly of all those which had wintered in East Africa. I cannot think that these flights were more than 1000 feet high. On the other hand, when standing on the highest peak in the Island of Palma, 6500 feet, with a dense mass of clouds beneath us, leaving nothing of land or sea visible, save the distant Peak of Tenerife, 13,000 feet, I have watched a flock of Cornish choughs soaring above us, till at length they were absolutely undistinguishable by us except with field-glasses.

As to the speed with which the migration flights are accomplished, they require much further observation. Herr Gätke maintains that godwits and plovers can fly at the rate of 240 miles an hour (!), and the late Dr. Jerdon stated that the spine-tailed swift (*Acanthyllis caudacutus*), roosting in Ceylon, would reach the Himalayas (1200 miles) before sunset. Certainly in their ordinary flight the swift is the only bird I have ever noticed to outstrip an express train on the Great Northern Railway.

Observation has shown us that, while there is a regular and uniform migration in the case of some species, yet that, beyond these, there comes a partial migration of some species, immigrants and emigrants simultaneously, and this, besides the familiar vertical emigration from higher to lower altitudes and *vice versâ*, as in the familiar instance of the lapwing and golden plover. There is still much scope for the field naturalist in observation of these partial migrations. There are also species in which some individuals migrate and some are sedentary, *e.g.* in the few primeval forests which still remain in the Canary Islands, and which are enshrouded in almost perpetual mist, the woodcock is sedentary, and not uncommon. I have often put up the bird and seen the eggs; but in winter the number is vastly increased, and the visitors are easily to be distinguished from the residents by their lighter colour and larger size. The resident never leaves the cover of the dense forest, where the growth of ferns and shrubs is perpetual, and fosters a moist, rich, semipeaty soil, in which the woodcock finds abundant food all the year, and has thus lost its migratory instincts.

But why do birds migrate? Observation has brought to light many facts which seem to increase the difficulties of a satisfactory answer to the question. The autumnal retreat from the breeding quarters might be explained by a want of sufficient sustenance as winter approaches in the higher latitudes, but this will not account for the return migration in spring, since there is no perceptible diminution of supplies in the winter quarters. A friend of mine, who was for some time stationed at an infirmary at Kikombo, on the high plateau south-east of Victoria Nyanza Lake, almost under the equator, where there is no variation in the seasons, wrote to me that from November to March the country swarmed with swallows and martins, which seemed to the casual observer to consist almost wholly of our three species, though occasionally a few birds of different type might be noticed in the larger flocks. Towards the end of March, without any observable change in climatic or atmospheric conditions, nine-tenths of the birds suddenly disappeared, and only a sprinkling remained. These, which had previously been lost amid the myriad of winter visitants, seemed to consist of four species, of which I received specimens of two, *Hirundo puella* and *H. senegalensis*. One, described as white underneath, is probably *H. æthiopica*; and the fourth, very small, and quite black, must be a *Psalidoprocne*. All these remained through spring and summer. The northward movement of all the others must be through some impulse not yet ascertained. In many other instances observation has shown that the impulse of movement is not dependent on the weather at the moment. This is especially the case with sea birds. Prof. Newton observes that they can be trusted as the almanack itself. Foul weather or fair, heat or cold, the puffins, *Fratercula arctica*, repair to some of their stations punctually on a given day, as if their movements were regulated by clockwork. In like manner, whether the summer be cold or hot, the swifts leave their summer home in England about the first week in August, only occasional stragglers ever being seen after that date. So in three different years I noticed the appearance of the common swift (*Cypselus apus*) in myriads on one day in the first week in April. In the case of almost all the land birds, it has been ascertained by repeated observations that the male birds arrive some days before the hens. I do not think it is proved that they start earlier; but, being generally stronger than the females, it is very natural that they should outstrip their weaker mates. I think, too, that there is evidence that those species which have the most extended southerly, have also the most extended northerly range. The same may hold good of individuals of the same species, and may be accounted for by, or account for, the fact that, *e.g.*, the individuals of the wheatear or of the willow wren which penetrate furthest north have longer and stronger wings than those individuals which terminate their journey in more southern latitudes. The length of wing of two specimens of *Saxicola œnanthe* in my collection from Greenland and Labrador exceeds by ·6 inch the length of British and Syrian specimens, and the next longest, exceeding them by ·5 inch, is from the Gambia. So the sedentary *Phylloscopus trochilus* of the Canaries has a perceptibly shorter wing than European specimens.

To say that migration is performed by instinct is no explanation of the marvellous faculty, it is an evasion of the difficulty. Prof. Möbius holds that birds crossing the ocean may be guided by observing the rolling of the waves, but this will not hold good in the varying storms of the Atlantic, still less in the vast stretch of stormy and landless ocean crossed by the bronze cuckoo (*Chrysococcyx lucidus*) in its passage from New Guinea to New Zealand. Prof. Palmén ascribes the due performance of the flight to experience, but this is not confirmed by field observers. He assumes that the flights are led by the oldest and strongest, but observation by Herr Gätke has shown that among migrants, as the young and old journey apart and by different routes, the former can have had no experience. All ornithologists are aware that the parent cuckoos leave this country long before their young ones are hatched by their foster-parents. The sense of sight cannot guide birds which travel by night, or span oceans or continents in a single flight. In noticing all the phenomena of migration, there yet remains a vast untilled region for the field naturalist.

What Prof. Newton terms the sense of direction, unconsciously exercised, is the nearest approach yet made to a solution of the problem. He remarks how vastly the sense of direction varies in human beings, contrasting its absence in the dwellers in towns compared with the power of the shepherd and the countryman, and, infinitely more, with the power of the savage or the Arab. He adduces the experience of Middendorff among the Samojeds, who know how to reach their goal by the shortest way through places wholly strange to them. He had known it among dogs and horses (as we may constantly perceive), but was surprised to find the same incomprehensible animal faculty unweakened among uncivilised men. Nor could the Samojeds understand his enquiry how they did it? They disarmed him by the question, How now does the arctic fox find its way aright on the Tundra, and never go astray? and Middendorff adds: "I was thrown back on the unconscious performance of an inherited animal faculty"; and so are we!

There is one more kind of migration, on which we know nothing, and where the field naturalist has still abundant scope for the exercise of observation. I mean what is called exceptional migration, not the mere wanderings of waifs and strays, nor yet the uncertain travels of some species, as the crossbill in search of food, but the colonising parties of many gregarious species, which generally, so far as we know in our own hemisphere, travel from east to west, or from south-east to north-west. Such are the waxwing (*Ampelis garrula*), the pastor starling (*Pastor roseus*) and Pallas's sandgrouse, after intervals sometimes of many years, or sometimes for two or three years in succession. The waxwing will overspread Western Europe in winter for a short time. It appears to be equally inconstant in its choice of summer quarters, as was shown by J. Wolley in Lapland. The rose pastor regularly winters in India, but never remains to breed. For this purpose the whole race seems to collect and travel north-west, but rarely, or after intervals of many years, returns to the same quarters. Verona, Broussa, Smyrna, Odessa, the Dobrudscha have all during the last half-century been visited for one summer by tens of thousands, who are attracted by the visitations of locusts, on which they feed, rear their young, and go. These irruptions, however, cannot be classed under the laws of ordinary migration. Not less inexplicable are such migrations as those of the African darter, which, though never yet observed to the north of the African lakes, contrives to pass, every spring, unobserved to the lake of Antioch in North Syria, where I found a large colony rearing their young, which, so soon as their progeny was able to fly, disappeared to the south-east as suddenly as they had arrived.

There is one possible explanation of the sense of direction unconsciously exercised, which I submit as a working hypothesis. We are all aware of the instinct, strong both in mammals and birds without exception, which attracts them to the place of their nativity. When the increasing cold of the northern regions, in which they all had their origin, drove the mammals southward, they could not retrace their steps, because the increasing polar sea, as the arctic continent sank, barred their way. The birds reluctantly left their homes as winter came on, and followed the supply of food. But as the season in their new residence became hotter in summer, they instinctively returned to their birthplaces, and there reared their young, retiring with them when the recurring winter impelled them to seek a warmer climate. Those species which, unfitted for a greater amount of heat by their more protracted sojourn in the northern regions, persisted in revisiting their ancestral homes, or getting as near to them as they could, retained a capacity for enjoying a temperate climate, which, very gradually, was lost by the species which settled down more permanently in their new quarters, and thus a law of migration became established on the one side, and sedentary habits on the other.

If there be one question on which the field naturalist may contribute, as lion's provider to the philosopher, more than another, it is on the now much disputed topic of "mimicry," whether protective or aggressive. As Mr. Beddard has remarked on this subject, "The field of hypothesis has no limits, and what we need is more study"—and, may we not add, more accurate observation of facts. The theory of protective mimicry was first propounded by Mr. H. W. Bates, from his observations on the Amazon. He found that the group of butterflies, *Heliconiidæ*, conspicuously banded with yellow and black, were provided with certain glands which secrete a nauseating fluid, supposed to render them unpalatable to birds. In the sand districts he found also similarly coloured butterflies, belonging to the family *Pieridæ*, which so closely resembled the others in shape and markings as to be easily mistaken for them, but which, unprovided with such secreting glands, were unprotected from the attacks of birds. The resemblance, he thought, was brought about by natural selection for the protection of the edible butterflies, through the birds mistaking them for the inedible kind. Other cases of mimicry among a great variety of insects have since been pointed out, and the theory of protective mimicry has gained many adherents. Among birds, many instances have been adduced. Mr. Wallace has described the extraordinary similarity between birds of very different families, *Oriolus bouruensis* and *Philemon moluccensis*, both peculiar to the island of Bouru. Mr. H. O. Forbes has discovered a similar brown oriole, *Oriolus decipiens*, as closely imitating the appearance of the *Philemon timorlaoensis* of Timor-laut. A similar instance occurs in Ceram. But Mr. Wallace observes that, while usually the mimicking species is less numerous than the mimicked, the contrary appears to be the case in Bouru, and it is difficult to see what advantage has been gained by the mimicry. Now, all the species of *Philemon* are remarkably sombre-coloured birds, and the mimicry cannot be on their side. But there are other brown orioles, more closely resembling those named, in other Moluccan islands, and yet having no resemblance to the *Philemon* of the same island, as may be seen in the case of the *Oriolus phæochromus* and *Philemon gilolensis* from Gilolo. Yet the oriole has adopted the same livery which elsewhere is a perfect mimicry. May it not therefore be that we have, in this group of brown orioles, the original type of the family undifferentiated? As they spread east and south we may trace the gradation, through the brown striation of the New Guinea bird, to the brighter, green-tinged form of the West Australian and the green plumage of the Southern Australian, while westward the brilliant yellows of the numerous Indian and African species were developed, and another group, preferring high elevations, passing through the mountain ranges of Java, Sumatra, and Borneo, intensified the aboriginal brown into black, and hence were evolved the deep reds of the various species which culminate in the crimson of Formosa, *Oriolus ardens*, and the still deeper crimsons of *O. trailli* of the Himalayas.

It is possible that there may be similarity without mimicry, and, by the five laws of mimicry as laid down by Wallace, very many suggested cases must be eliminated. We all know that it is quite possible to find between species of very different genera extraordinary similarity which is not mimetic. Take, for instance, the remarkable identity of coloration in the case of some of the African species *Macronyx* and the American *Sturnella*, or, again, of some of the African *Campophagæ* and the American *Agelæus*. The outward resemblance occurs in both cases in the red as well as in the yellow-coloured species of all four groups. But we find that the *Macronyx* of America and the *Campophagæ* of Africa, in acquiring this coloration, have departed widely from the plain colour found in their immediate relatives. If we applied Mr. Scudder's theory on insects, we must imagine that the prototype form has become extinct, while the mimicker has established its position. This is an hypothesis which is easier to suggest than either to prove or to disprove. Similar cases may frequently be found in botany. The strawberry is not indigenous in Japan, but in the mountains there I found a potentilla in fruit which absolutely mimicked the Alpine strawberry in the minutest particulars, in its runners, its blossoms, and fruit; but the fruit was simply dry pith, supporting the seeds and retaining its colour without shrinking or falling from the stalk for weeks—a remarkable case, we cannot say of unconscious mimicry, but of unconscious resemblance. Mimicry in birds is comparatively rare, and still rarer in mammals, which is not surprising when we consider how small is the total number of the mammalia, and even of birds, compared with the countless species of invertebrates. Out of the vast assemblage of insects, with their varied colours and patterns, it would be strange if there were not many cases of accidental resemblance. A strict application of Wallace's five laws would, perhaps, if all the circumstances were known, eliminate many accepted instances.

As to cases of edible insects mimicking inedible, Mr. Poulton admits that even unpalatable animals have their special enemies, and that the enemies of palatable animals are not indefinitely numerous.

Mr. Beddard gives tables of the results obtained by Weismann, Poulton, and others, which show that it is impossible to lay down any definite law upon the subject, and that the likes and dislikes of insect-eating animals are purely relative.

One of the most interesting cases of mimicry is that of the *Volucella*, a genus of *Diptera*, whose larvæ live on the larvæ of *Hymenoptera*, and of which the perfect insect closely resembles some species of humble-bee. Though this fact is unquestioned, yet it has recently given rise to a controversy, which, so far as one who has no claim to be an entomologist can judge, proves that while there is much that can be explained by mimicry, there is, nevertheless, a danger of its advocates pressing it too far. *Volucella bombylans* occurs in two varieties, which prey upon the humble-bees, *Bombus muscorum* and *B. lapidarius*, which they respectively resemble. Mr. Bateson does not question the behaviour of the *Volucella*, but states that neither variety specially represents *B. muscorum*, and yet that they deposit their eggs more frequently in their nests than in the nests of other species which they resemble more closely. He also states that in a show-case in the Royal College of Surgeons, to illustrate mining, two specimens of another species, *B. sylvarum*, were placed alongside of the *Volucella*, which they do resemble, but were labelled *B. muscorum*.

But Mr. Hart explains the parasitism in another way. He states that a nest of *B. muscorum* is made on the surface, without much attempt at concealment, and that the bee is a peculiarly gentle species, with a very feeble sting; but that the species which the *Volucella* most resemble are irascible, and therefore more dangerous to intruders. If this be so, it is difficult to see why the *Volucella* should mimic the bee, which it does not affect, more closely than the one which is generally its victim. I do not presume to express any opinion further than this, that the instances I have cited show that there is much reason for further careful observation by the field naturalist, and much yet to be discovered by the physiologist and the chemist, as to the composition and nature of animal pigments.

I had proposed to occupy a considerable portion of my address with a statement of the present position of the controversy on heredity, by far the most difficult and important of all those subjects which at present attract the attention of the biologist; but an attack of illness has compelled me to abandon my purpose. Not that I proposed to venture to express any opinions of my own, for, with such protagonists in the field as Weismann, Wallace, Romanes, and Poulton on the one side, and Herbert Spencer and Hartog on the other, "*Non nostrum inter vos tantas componere lites.*"

So far as I can understand Weismann's theory, he assumes the separation of germ cells and somatic cells, and that each germ cell contains in its nucleus a number of "ids," each "id" representing the personality of an ancestral member of the species, or of an antecedent species. "The first multicellular organism was probably a cluster of similar cells, but these units soon lost their original homogeneity. As the result of mere relative position, some of the cells were especially fitted to provide for the nutrition of the colony, while others undertook the work of reproduction." The latter, or germ-plasm, he assumes to possess an unlimited power of continuance, and that life is endowed with a fixed duration, not because it is contrary to its natuure to be unlimited, but because the unlimited existence of individuals would be a luxury without any corresponding advantage.

Herbert Spencer remarks upon this: "The changes of every aggregate, no matter of what kind, inevitably end in a state of equilibrium. Suns and planets die, as well as organisms." But has the theory been proved, either by the histologist, the microscopist, or the chemist? Spencer presses the point that the immortality of the protozoa has not been proved. And, after all, when Weismann makes the continuity of the germ plasm the foundation of a theory of heredity, he is building upon a pure hypothesis.

From the continuity of the germ-plasm, and its relative segregation from the body at large, save with respect to nutrition, he deduces, *à priori*, the impossibility of characters acquired by the body being transmitted through the germ-plasm to the offspring. From this he implies that where we find no intelligible mechanism to convey an imprint from the body to the germ, there no imprint can be conveyed. Romanes has brought forward many instances which seem to contradict this theory, and Herbert Spencer remarks that "a recognised principle of reasoning—'the law of parsimony'—forbids the assumption of more causes than are needful for the explanation of phenomena. We have evident causes which arrest the cell multiplication, therefore it is illegitimate to ascribe this arrest to some property inherent in the cells."

With regard to the reduction or disappearance of an organ, he states "that when natural selection, either direct or reversed, is set aside, why the mere cessation of selection should cause decrease of an organ, irrespective of the direct effects of disease, I am unable to see. Beyond the production of changes in the size of parts, by the selection of fortuitously arising variation, I can see but one other cause for the production of them—the competition among the parts for nutriment. . . . The active parts are well supplied, while the inactive parts are ill supplied and dwindle, as does the arm of the Hindu fakir. This competition is the cause of economy of growth—this is the cause of decrease from disease."

I may illustrate Mr. Herbert Spencer's remarks by the familiar instance of the pinions of the Kakapo (*Stringops*)—still remaining, but powerless for flight.

As for acquired habits, such as the modification of bird architecture by the same species under changed circumstances, how they can be better accounted for than by hereditary transmitted instinct, I do not see. I mean such cases as the ground-nesting *Didunculus* in Samoa having saved itself from extinction since the introduction of cats, by roosting and nesting in trees; or the extraordinary acquired habit of the black-cap in the Canaries, observed by Dr. Lowe, of piercing the calyx of *Hibiscus rosa-sinensis*—an introduced plant—to attract insects, for which he quietly sits waiting. So the lying low of a covey of partridges under an artificial kite would seem to be a transmitted instinct from a far-off ancestry not yet lost; for many generations of partridges, I fear, must have passed since the last kite hovered over the forefathers of an English partridge, save in very few parts of the island.

I cannot conclude without recalling that the past year has witnessed the severance of the last link with the pre-Darwinian naturalists in the death of Sir Richard Owen. Though never himself a field-worker, or the discoverer of a single animal living or extinct, his career extends over the whole history of palæontology. I say palæontology, for he was not a geologist in the sense of studying the order, succession, area, structure, and disturbance of strata. But he accumulated facts on the fossil remains that came to his hands, till he won the fame of being the greatest comparative anatomist of the age. To him we owe the building up of the skeletons of the giant *Dinornithidæ* and many other of the perished forms of the gigantic sloths, armadilloes, and mastodons of South America, Australia, and Europe. He was himself a colossal worker, and he never worked for popularity. He had lived and worked too long before the Victorian age to accept readily the doctrines which have revolutionised that science, though none has had a larger share in accumulating the facts, the combination of which of necessity produced that transformation. But, though he clung fondly to his old idea of the archetype, no man did more than Owen to explode the rival theories of both Wernerians and Huttonians, till the controversies of Plutonians and Neptunians came to us from the far past with as little to move our interest as the blue and green controversies of Constantinople.

Nor can we forget that it is to Sir Richard's indomitable perseverance that we owe the magnificent palace which contains the national collections in Cromwell Road. For many years he fought the battle almost alone. His demand for a building of two stories, covering five acres, was denounced as audacious. The scheme was pronounced foolish, crazy, and extravagant; but, after twenty years' struggle, he was victorious, and in 1872 the Act was passed which gave not five, but more than seven acres for the purpose. Owen retired from its direction in 1883, having achieved the crowning victory of his life. Looking back in his old age on the scientific achievements of the past, he fully recognised the prospects of still further advances, and observed, "The known is very small compared with the knowable, and we may trust in the Author of all truth, who, I think, will not let that truth remain for ever hidden."

I have endeavoured to show that there is still room for all workers, that the naturalist has his place, though the morphologist and the physiologist have rightly come into far greater prominence, and we need not yet abandon the field-glass and the lens for the microscope and the scalpel. The studies of the laboratory still leave room for the observations of the field. The investigation of muscles, the analysis of brain tissue, the research into the chemical properties of pigment, have not rendered worthless the study and observation of life and habits. As you cannot diagnose the Red Indian and the Anglo-Saxon by a comparison of their respective skeletons or researches into their muscular structure, but require to know the habits, the language, the modes of thought of each; so the mammal, the bird, and even the invertebrate, has his character, his voice, his impulses, aye, I will add, his ideas, to be taken into account in order to discriminate him. There is something beyond matter in life, even in its lowest forms. I may quote on this the caution uttered by a predecessor of mine in this chair (Prof. Milnes Marshall): "One thing above all is apparent, that embryologists must not work single-handed; must not be satisfied with an acquaintance, however exact, with animals from the side of development only; for embryos have this in common with maps, that too close and too exclusive a study of them is apt to disturb a man's reasoning power."

The ancient Greek philosopher gives us a threefold division of the intellectual faculties—φρόνησις, ἐπιστήμη, σύνεσις—and I think we may apply it to the subdivision of labour in natural science: φρόνησις, ἡ τὰ καθ' ἕκαστα γνωρίζουσα, , is the power that divides, discerns, distinguishes—*i.e.* the naturalist; σύνεσις, the operation of the closest zoologist, who investigates and experiments; and ἐπιστήμη, the faculty of the philosopher, who draws his conclusions from facts and observations.

The older naturalists lost much from lack of the records of previous observations; their difficulties were not ours, but they went to nature for their teachings rather than to books. Now we find it hard to avoid being smothered with the literature on the subject, and being choked with the dust of libraries. The danger against which Prof. Marshall warns the embryologist is not confined to him alone; the observer of facts is equally exposed to it, and he must beware of the danger, else he may become a mere materialist. The poetic, the imaginative, the emotional, the spiritual, all go to make up the man; and if one of these is missing, he is incomplete.

I cannot but feel that the danger of this concentration upon one side only of nature is painfully illustrated in the life of our great master, Darwin. In his early days he was a lover of literature, he delighted in Shakespeare and other poets; but after years of scientific activity and interest, he found on taking them up again that he had not only grown indifferent to them, but that they were even distasteful to him. He had suffered a sort of atrophy on that side of his nature, as the disused pinions of the Kakapo have become powerless—the spiritual, the imaginative, the emotional, we may call it.

The case of Darwin illustrates a law—a principle we may call it—namely, that the spiritual faculty lives or dies by exercise or the want of it even as does the bodily. Yet the atrophy was unconscious. Far was it from Darwin to ignore or depreciate studies not his own. He has shown us this when he prefixed to the title-page of his great work the following extract from Lord Chancellor Bacon: "To conclude, therefore, let no man, out of a weak conceit of sobriety, or an ill-applied moderation, think or maintain that a man can search too far, or be too well studied in the book of God's word, or in the book of God's works, divinity or philosophy, but rather let men endeavour an endless progress or proficience in both." In true harmony this with the spirit of the father of natural history, concluding with the words, "O Lord, how manifold are Thy works, in wisdom hast Thou made them all, the earth is full of Thy riches."

SECTION G.

MECHANICAL SCIENCE.

OPENING ADDRESS BY JEREMIAH HEAD, M.INST.C.E., PAST PRES.INST.MECH.E., F.C.S., PRESIDENT OF THE SECTION.

THIS Section of the British Association for the Advancement of Science was founded with the object of making more widely known, and more generally appreciated, all well-ascertained facts and well-established principles having special reference to mechanical science.

As President of the Section for the year, it becomes my duty to inaugurate the proceedings by addressing you upon some portion of the scientific domain to which I have referred, and in which your presence here indicates that you are all more or less interested.

Mechanical Science.

The founders of the British Association no doubt regarded the field of operations which they awarded to Section G as a not less purely scientific one than those which they allotted to the other Sections. And indeed, mechanical science studied, say, by Watt was as free from suspicion of commercial bias as chemical science studied, say, by Faraday.

But whatever may have been the original idea, the practice of the Section has recently been to expend most of its available time in the consideration of more or less beneficial applications of mechanical science, rather than of the first principles thereof. Our Section has become more and more one of applied rather than of pure science. None of the other Sections is free from this fault, if fault it be (which I do not contend or admit), but Section G seems to me to be beyond all question, and beyond all others, the Section of applied science.

The charter of the Institution of Civil Engineers commences by reciting that the object of that society is "the general advancement of mechanical science, and more particularly for promoting the acquisition of that species of knowledge which constitutes the profession of a civil engineer, being the art of directing the great sources of power in nature for the use and convenience of man."

It seems that in 1828, when the Institution was incorporated, the term "mechanical science" had a wider meaning than it is now usually understood to have. For, according to the charter, the art of directing the great sources of power in nature is only a particular species of knowledge which "mechanical science" includes.

In 1836, or eight years later, the founders of our Section adopted the term without again defining it. Probably they accepted the careful definition of the Great George Street Institution. Time has shown the wisdom of that decision. For we civil engineers and other frequenters of Section G in active practice need far more knowledge than mechanical science can teach us in the ordinary or narrow sense of the term. Our art in its multifarious branches requires, if success is to be attained, the acquisition and application of almost all the other sciences which belong to the fields of research relegated to the other Sections. For how could the gigantic engineering structures of modern times be designed without recourse to mathematics, or steam and other motors without a knowledge of physics, or modern metallurgical operations be conducted without chemistry, or mining without geology, or communications by rail, ship, and wire be established and carried on with all parts of the world without attention to geography, or extensive manufacturing enterprises be developed if the laws of economics were neglected?

As to biological studies, they seem at first sight to have but little to do with mechanical science. It might even be thought that the civil engineer could afford altogether to neglect this part of the work of the Association. But I trust I shall be able to show you before I finish that any such view is absolutely untenable.

Mechanisms in Nature.

Indeed, I hope, in the course of this address, to satisfy you that mechanical science is largely indebted to mechanisms as they exist in nature, if not for its origin, at all events for much of its progress hitherto, and that nature must still be our guide.

Mechanical science has been built up entirely upon observation and experiment, and the natural laws which have been induced therefrom by man. The lower animals in their wild condition work with tools or appliances external to their bodies to but a very slight extent, and man in a primitive or savage state does the same. But many, if not most, animals can be taught to use mechanisms if carefully trained from infancy. Thus, the well-known donkey at Carisbrooke Castle draws water from a deep well by a treadmill arrangement just as well as a man could do it. He watches the rope on the barrel till the full pail rises above the parapet of the well, then slacks back a little to allow it to be rested thereon, and only then leaves the drum and retreats to his stable. But, according to his attendant, four years were needed for his education, and unless it had been commenced early it would have been useless.

I have seen a canary gradually lift from a little well, situated a foot below its perch, a thimble full of water by pulling up with its beak, bit by bit, a little chain attached to it, and securing each length lifted with its foot till it could take another pull. When the thimble reached its perch level the bird took a drink, and then let it fall back into the well. Numerous other examples will doubtless occur to you.

But though animals can be taught to make use of mechanical appliances provided for them—a fact which shows the existence in their brains of a faculty corresponding in kind, if not in degree, to the mechanical faculty in man—they rarely, on their own initiative, make use of anything external to their bodies as tools; and still more rarely, if ever, do they make, alter, or adapt such mechanical aids. Mr. C. Wood, of Middlesbrough, informs me that certain crows which frequent oyster-beds on the coast of India, wait until the receding tide uncovers the oysters, which still remain open for a time. A crow will then put a pebble inside one, and, having thus gagged it and secured its own safety, will proceed to pick it out and eat it at leisure. A monkey will crack a nut between two stones, and will hurl missiles at his enemies. But in some countries he is systematically entrapped by tying to a tree a hollow gourd containing rice, and having a hole large enough for his hand, but too small for his clenched fist, to pass through. He climbs the tree and grasps the rice, and remains there till taken, being too greedy, and not having sufficient sense, to let go the rice and withdraw his hand.

This is on a par with the snuff-taking imbecile, described by Hugh Miller ("My Schools and Schoolmasters)," whom the boys used to tease by giving him a little snuff at the bottom of a deep tin box. The imbecile would try to get at it for hours without the idea ever occurring to him that he might achieve his object by turning the box upside down.

All animals are, however, in their bodily frames, and in the intricate processes and functions which go on continuously therein, mechanisms of so elaborate a kind that we can only look and wonder and strive to imitate them a little here and there. The mechanism of their own bodily frames is that with which the lower animals have to be content, and whilst they are in the prime of life and health, and in their natural environment, it is generally sufficient for all their purposes. Man has a still more perfect, or rather a still more versatile bodily mechanism, and one which in a limited environment would be equally sufficient for his needs. But he has also an enterprising and powerful mind which impels him to strive after and enables him to enjoy fields of conquest unknown to, and uncared for by, the relatively brainless lower animals.

Urged on by these superior mental powers, man must soon have perceived that by the use of instruments he could more quickly and easily gain his ends, and he would not be long in discovering that certain other animals, such as the ox and the horse, were teachable and his willing slaves, provided only he fed and trained them, and treated them kindly.

First, in common with other animals, he would find out that stones and sticks were of some use as weapons and tools; then he would go further and utilise skins and thongs for clothing and harness; and by selecting and modifying his stones and sticks he would form them into rough implements, which would enable him to cut down trees and to make rude huts and boats. Animals caught and domesticated would first be taught to haul light logs along the ground, then to move heavier ones on rollers; and later, in order to avoid the necessity for continual replacement on the rollers, the wheel and axle would be gradually developed.

The mechanical nomenclature of all languages is largely derived from the bodies of men and other animals. From this it is clear that animals have always been recognised as mechanisms, or as closely related thereto. The names borrowed from them generally indicate a resemblance in form rather than in function, though not invariably so.

Thus in our own language we have the "head" of a ship, a river, a lake, a jetty, a bolt, a nail, a screw, a rivet, a flight of stairs, and a column of water; the brow of an incline; the crown of an arch; the toe of a pier; the foot of a wall; the forefoot, heel, ribs, waist, knees, skin, nose, and dead eyes of a ship; also turtle backs and whale backs; the jaws of a vice: the claws of a clutch; the teeth of wheels; necks, shoulders, eyes, nozzles, legs, ears, mouths, lips, cheeks, elbows, feathers, tongues, throats, and arms; caps, bonnets, collars, sleeves, saddles, gussets, paddles, fins, wings, horns, crabs, donkeys, monkeys, and dogs; flywheels, running nooses, crane necks, grasshopper engines, &c.

Not only has our mechanical nomenclature been largely taken from animals, but many of our principal mechanical devices have pre-existed in them. Thus, examples of levers of all three orders are to be found in the bodies of animals. The human foot contains instances of the first and second, and the forearm of the third order of lever. The patella, or knee-cap, is practically a part of a pulley. There are several hinges and some ball-and-socket joints, with perfect lubricating arrangements. Lungs are bellows, and the vocal organs comprise every requisite of a perfect musical instrument. The heart is a combination of four force-pumps acting harmoniously together. The wrist, ankle, and spinal vertebræ form universal joints. The eyes may be regarded as double-lens cameras, with power to adjust focal length, and able, by their stereoscopic action, to gauge size, solidity, and distance. The nerves form a complete telegraph system with separate up and down lines and a central exchange. The circulation of the blood is a double-line system of canals, in which the canal liquid and canal boats move together, making the complete circuit twice a minute, distributing supplies to wherever required, and taking up return loads wherever ready without stopping. It is also a heat-distributing apparatus, carrying heat from wherever it is generated or in excess to wherever it is deficient, and establishing a general average, just as engineers endeavour, but with less success, to do in houses and public buildings. The respiratory system may be looked upon as that whereby the internal ventilation of the bodily structure is maintained. For by it oxygen is separated from the air and imparted to the blood for conveyance and use where needed, whilst at the same time the products of combustion are extracted therefrom and discharged into the atmosphere.

Mastication, which is the first process in the alimentary system, is, or rather should be, a perfect system of cutting up and grinding, and to assist and save animal, and especially human, mastication is the chief aim and object of all the gigantic milling establishments of modern times. The later alimentary processes are rather chemical than mechanical, but still the successive muscular contractions, whereby the contents of the canal are forced through their intricate course, are distinctly mechanical, and may have suggested the action of various mechanisms which are used in the arts to operate on plastic materials, and cause them to flow into new forms and directions.

The superiority of man to the lower animals can only have become conspicuous and decided when he began to use his inventive faculties and to fashion weapons and implements of a more efficient kind than the sticks and stones which they also occasionally use.

But human races and individuals were never equally endowed by nature. Some individuals would have greater inventive powers than others, and these and their posterity would gradually become dominant races. Large masses of mankind are still more or less in the position of primeval man, which, if we accept the conclusions of Darwin, Lubbock, and other modern men of science, we must regard as one of barbarism. For they are still without tools, appliances, and clothes, except of the most elementary kinds, and mechanical science might almost be non-existent, so far as they are concerned.[1]

It would obviously be impossible for me to treat of or call attention even to an infinitesimal extent to the results of mechanical science which surround us now so profusely, and which make our life so different from that of primeval man; and, even if it were possible, it would be quite unnecessary. We have all grown up in a mechanical age. We are so familiarised with artificial aids that we have come to regard them as part of our natural environment, and their occasional absence impresses us far more than their habitual presence.

I propose, with your leave, to proceed to the consideration of how far man is, in his natural condition, and has become by aid of mechanical science, able to compete successfully with other and specially endowed animals, each in its own sphere of action.

Bodily Powers of Man and other Animals.

The bodily frame of man is adapted for life and movement only on or near to the surface of the earth. Without mechanical aids he can walk for several hours, at a speed which is ordinarily from 3 to 4 miles per hour. Under exceptional circumstances he has accomplished over 8 miles ("Whitaker's Almanack," 1893, p. 395) in one hour, and an average of

[1] Mr. H. L. Lapage, M.Inst.C.E., who has just returned from Western Australia, states that he found the natives of both sexes and all ages absolutely nude.

$2\frac{3}{4}$ miles per hour for 141 hours.[1] In running he has covered about $11\frac{1}{2}$ miles in an hour. In water he has proved himself capable of swimming 100 yards at the rate of 3 miles per hour, and 22 miles at rather over 1 mile per hour. He can easily climb the most rugged mountain path and descend the same. He can swarm up a bare pole or a rope, and when of suitable physique and trained from infancy can perform those wonderful feats of strength and agility which we are accustomed to expect from acrobats. He has shown himself able to jump as high as 6 feet $2\frac{3}{4}$ inches from the ground, and over a horizontal distance of 23 feet 3 inches, and has thrown a cricket-ball as far as $382\frac{1}{2}$ feet before it struck the ground. (*Chambers' Encyclopædia*, "Athletic Sports.")

The attitude and action of a man in throwing a stone or a cricket-ball, where he exerts a considerable force at several feet from the ground, to which the reaction has to be transmitted and to which he is in no way fastened, are unequalled in any artificial machine. The similar but contrary action of pulling a rope horizontally, as in "tug of war" competitions, is equally remarkable.

So also the power of the living human mechanism to withstand widely diverse and excessive strains is altogether unapproachable in artificial constructions. Thus, although fitted for an external atmospheric pressure of about 15 lbs. to the square inch, he has been enabled, as exemplified by Messrs. Glaisher and Coxwell in 1862, to ascend to a height of seven miles, and breathe air at a pressure of only $3\frac{1}{2}$ lbs. per square inch, and still live. And, on the other hand, divers have been down into water 80 feet deep, entailing an extra pressure of about 36 lbs. per square inch, and have returned safely. One has even been to a depth of 150 feet, but the resulting pressure of 67 lbs. per square inch cost him his life. (*Pall Mall Gazette*, July 5, 1893, p. 8.)

Recent fasting performances (if the published records are to be trusted) are not less remarkable when we are comparing the human body as a piece of mechanism with those of artificial construction. For what artificial motor could continue its functions forty days and nights without fuel, or, if the material of which it was constructed were gradually consumed to maintain the flow of energy, could afterwards build itself up again to its original substance?

These and other performances are, when considered individually and separately, often largely exceeded by other animals specially adapted to their own limited spheres of activity. The marvel is not, therefore, that the human bodily mechanism is capable of any one kind of action, but that, in its various developments, it can do all or any of them, and also carry a mind endowed with far wider powers than any other animal.

Animals other than man are also adapted for life and movement on or about the surface of the earth. This includes a certain distance below the ground, as in the case of earthworms; under the water, as in the case of fish; on the water, as in the case of swimming birds; and in the air, as with flying birds.

As far as I know, no animal burrows downwards into the earth to a greater depth than 8 feet ("Vegetable Mould and Earthworms," by Charles Darwin, p. 111), and then only in dry ground. Man is naturally very ill-adapted for boring into the earth as the earthworm does. Indeed, without mechanical aids he would be helpless in excavating or in dealing with the accumulations of water which are commonly met with underground. But by aid of the steam-engine for pumping, for air-compressing, ventilating, hauling, rock-boring, electric lighting, and so forth, and by the utilisation of explosives, he has obtained a complete mastery over the crust of the earth and its mineral contents, down to the depth where, owing to the increase of temperature, the conditions of existence become difficult to maintain.

I have said that on land, man, unaided by mechanism, has been able to cover about $11\frac{1}{2}$ miles in one hour. Two miles he has been able to run at the rate of nearly 13 miles per hour, and 100 yards at the rate of over 20 miles per hour. (*Chambers' Encyclopædia*, "Athletic Sports.") But the horse, though he cannot walk faster than man, nor exceed him in jumping heights or distances, can certainly beat him altogether when galloping or trotting. A mile has been galloped in 103 seconds, equal to 35 miles per hour; and has been trotted in 124 seconds, equal to 29 miles per hour. (*Chambers' Encyclopædia*, "Horse.")

There are many other animals, such as ostriches, greyhounds, antelopes, and wolves, which run at great speeds, but reliable records are difficult to obtain, and are scarcely necessary for our present purpose.

[1] Recent pedestrian race from Berlin to Vienna.

Mechanical Aid without Extraneous Motive-power.

Let us now consider how man's position as a competitor with other animals in speed is affected by his use of mechanical aids, but without any extraneous motive-power.

Locomotion on Land.—Where there is a stretch of good ice, and he is able to bind skates on his feet, he can thereby largely augment his running speed. This was exemplified by the winner of the match for amateurs at Haarlem last winter, who accomplished the distance of 3·1 miles at the rate of about 21 miles per hour.

But the most wonderful increase to the locomotive power of man on land is obtained by the use of the modern cycle. Cycling is easily performed only where roads, wind, and weather are favourable. But similar conditions must also be present to secure the best speed of horses, with which we have been making comparison. One mile has been cycled at the rate of 27·1 miles per hour ("Whitaker's Almanack," 1893), 50 at 20, 100 at 16·6 (*Chambers' Encyclopædia*, "Cycling"), 388 at 12·5 (*Times*, September 26 to October 7, 1892), and 900 at 12·43 ("Whitaker's Almanack," 1893), miles per hour.

The recent race between German and Austrian cavalry officers on the high road between Vienna and Berlin has afforded an excellent opportunity to judge of the speed and endurance of horses as compared with men over long distances. Count Starhemberg, the winner, performed the distance, about 388 miles, in 71·33 hours, equal to 5·45 miles per hour. He rested only one hour in twelve. His horse, though successful, has since died. (Vienna Berlin Race, June, 1893.)

Lawrence Fletcher cycled, also along the high roads, from Land's End to John o' Groat's house, 900 miles, in 72·4 hours, equal to 12·43 miles per hour, or more than double the distance that the Count rode, and at above double the speed. To the best of my knowledge he still lives, and is no worse for his effort. The horse in this case would have to carry extra weight equal to one-sixth of his own, and the cyclist equal to a quarter of his own. But the horse carried himself and his rider on his own legs, while the cyclist made his machine bear the weight of itself and rider. Herein was probably the secret of his easy victory.

With the very remarkable exception of long-distance cycling, which is of limited application, man, relying on his own bodily strength, cannot successfully compete with other animals which, like the horse, are specially fitted for rapid land locomotion. His only alternatives are either to utilise the horse and ride or drive him, and so get the benefit of his superior strength and speed, or to use his own inventive faculty and construct appliances altogether apart from animal mechanisms. In either case he virtually gives up the contest as a self-moving animal, and to a great extent abandons himself to be carried by others or by inanimate machinery.

Nearly seventy years ago mankind came to this conclusion, and the modern railway system is the result. The locomotive will go at least double the speed of the race-horse. It will carry not only itself, but three or four times its own weight in addition, and will go, not two or three, but 100 miles or more without stopping, if only the road ahead be clear. And the iron horse is fed and controlled without even so much exertion as that put forth by a man on a horse of flesh and bone.

Locomotion in Water.—Let us now consider the powers of man relatively to other animals in moving upon and through the great waters with which three-fourths of the earth's surface is covered. Here he is in competition with fishes, aquatic mammals, and swimming birds.

I have already stated that, unaided by mechanism, he has shown himself able to swim for short distances at the rate of three, and long distances (22 miles) at the rate of one mile per hour. He has also given instances of being able to remain under water for $4\frac{1}{2}$ minutes. ("Whitaker's Almanack," 1893.)

Credible eye-witnesses inform me that porpoises easily overtake and keep pace with a steamer going $12\frac{1}{2}$ knots, or, say, over 14 miles per hour, for an indefinite length of time. This is five and fifteen times the maximum swimming speed of a man for short and long distances respectively. No doubt the form and surface of a fish, whose main business is swimming, offer less resistance, and his muscular power is more concentrated and better applied towards propulsion in water than is the case with man, whose body is also adapted for so many other purposes.

I am further informed by Mr. Nelson, of Redcar, a naturalist who has made the experiment, that it is impossible for an ordinary sea-boat rowed by two men, and going at five miles per hour, to overtake the aquatic bird called the Great Northern Diver, when endeavouring to make his escape by alternately swimming on the surface and diving below. His speed is therefore nearly double the short and five times the long distance speed of unaided man in water. As regards remaining under water, fishes properly so-called have unlimited powers, and even aquatic mammals, such as whales, can remain under for 1½ hours.

Using only his own strength, but assisting himself with mechanical devices, man has been able to increase considerably his speed as a swimming animal. Mr. John McCall, of Walthamstow, informs me that in 1868 he constructed and repeatedly used an apparatus which acted like the tail of a fish. It consisted of a piece of whalebone, having a broad yet thin and elastic blade, tapering into a shank like the end of an oar. The blade was 15 inches wide and 4 feet long, including the shank. To the end of the latter a horizontal cross-bar 13 inches long was fitted, and leather pockets were provided at the ends for the feet. By swimming on his back and striking out alternately with his legs, he was able, with the assistance of this apparatus, to keep up with a sea-boat pulled by two men at about 4 miles per hour.

By means of boats, which he propels by oars or sculls, and notwithstanding the increased weight, and therefore displacement, involved by them, man has been able to increase his speed on the surface of the water to a maximum of about 12 miles per hour for about 4 miles distance, under favourable circumstances. So, by supplementing his bodily powers by means of mechanical aids, such as the diving-bell and the diving-helmet, dress, and air-pump, or by the portable self-acting apparatus used with such good effect in the construction of the Severn tunnel, man has been able to approach very nearly to the natural diving powers of, at all events, aquatic mammals, except that he cannot move about in subaqueous regions with anything approaching their ease and celerity.

Invariably on water, as almost invariably on land, man is quite unable to compete in power of locomotion with other specially adapted animals, whether or not he avails himself of mechanical aids, so long as his own bodily strength is the only motive-power he employs. He has gradually come to recognise this fact, and to see that he must use this inventive faculties and find new and powerful motors external to himself if he would really claim to dominate the great waters of the earth.

The fastest mechanism of any size, animal or man-made, which, as far as I know, has ever cut its way through the waters for any considerable distance is the torpedo-boat, *Ariete*, made by Messrs. Thornycroft and Son, of London, in 1887. It has a displacement or total weight of about 110 tons, and machinery capable of exerting 1290 effective horse-power, or 11·7 horse-power per ton of weight or displacement; or, to put it in another form, an effective horse-power is by it obtained from a weight of 191 lbs., which includes vessel, machinery, fuel, stores, and attendants. The speed accomplished at the trials of this little craft, being the average of six one-mile tests, was 26·18 knots, or 30·16 miles per hour (*Engineering*, July 15, 1887). As might be expected, it resembles a fish, in that its interior is almost exclusively devoted to the machinery and accessories necessary for propulsion. During the trials the water, fuel, stores, and other ponderable substances carried amounted to 17·35 tons. Two similar boats were able to make the voyage to South America by themselves, though at much lower speed and replenishing their fuel on the way. No fish or swimming bird can match this performance. And inasmuch as 191 lbs. of dead weight produced 1 horse-power, as compared with from 150 to 250 lbs. in certain flying birds, it would seem that with suitable adaptations the *Ariete* might even have been made to navigate the air instead of the water.[1] But I will revert to this subject later on.

Where safety in any weather, and passenger and cargo carrying powers are aimed at, as well as, or prior to, the utmost attainable speed—and these must ever be the leading features of ocean-transit steamers if they are to attain commercial success—there I must refer you to those magnificent examples of naval architecture which are more or less familiar to you all, and of which we, as a maritime nation, are so justly proud. If, for example, we turn our attention for a moment to the new Cunard liners, the *Campania* and *Lucania*, having each a weight or displacement of 18,000 tons and 24,000 effective horse-power, or 1·33 horse-power per ton of displacement, we shall find that, with the commercial advantages alluded to, they obtain a maximum speed of 22·5 knots, or about 26 miles per hour.

If, instead of 1·33 effective horse-power per ton of displacement, they were provided with eight times that amount, or 10·64 horse-power per ton, thereby sacrificing passenger and cargo accommodation and making them nearly as full of propelling machinery as the *Ariete* torpedo-boat, and if it were then found possible to apply this enormous power effectively, then there is every reason to believe they would accomplish for short distances double the speed, or, say, 45 knots, or about 52 statute miles per hour.

By inventing and utilising mechanical contrivances entirely independent of his own bodily strength, man can now pass over the surface of the waters at the rate of over 500 knots per day, and at the same time retain the comforts and conveniences of life as though he were on shore. He has in this way beaten the natural and specially fitted denizens of the deep in their own element, as regards speed and continuity of effort. But he is still behind them as to safety. We do not find that fishes or aquatic mammals often perish in numbers, as man does, by collisions in fogs, or by being cast on lee shores and rocks by stress of weather. Shall we ever arrive at the point of making ocean travelling absolutely safe? The Cunard Company is able to boast that from its commencement, fifty-three years ago, it has never lost a passenger's life or a letter, a statement which gives ground for hope that almost absolute safety is attainable. But, on the other hand, other owners of almost equal repute (not excluding the British Admiralty) are ever and anon losing magnificent vessels on rocks, in collisions, by fire, and even by stress of weather, in a way which makes us doubt whether it is possible for Britannia or any one else really to "rule the waves."

In one way the chances of serious disaster have been of late largely diminished, and here, again, Nature has been our teacher. The bodies of all animals except the very lowest are symmetrically formed on either side of a central longitudinal plane. Each important limb is in duplicate, and if one side is wounded the other can still act. We have at last found out the enormous advantage and increased safety of having the whole of our ship-propelling machinery in duplicate, and our ships made almost unsinkable by one longitudinal and numerous transverse bulkheads.

Locomotion in Air.—I now come to consider what is the position of man as regards locomotion in and through the great atmospheric envelope which surrounds the earth, in comparison with animals specially fitted by Nature for such work.

Nature seems never to bestow all her gifts on one individual or class of animals, and she never leaves any entirely destitute. For instance, the serpent, having no limbs whatever, would seem at first sight to be terribly handicapped; yet, in the language of the late Prof. Owen, "it can out-climb the monkey, out-swim the fish, out-leap the jerboa, and, suddenly loosing the close coils of its crouching spiral, it can spring in the air and seize the bird on the wing." (Pettigrew on "Animal Locomotion"). Here we have the spiral spring in nature before it was devised by man.

Flying animals seem to conform remarkably to this law. Thus we have birds like the penguin, which dive and swim but cannot fly; others, like the gannet, which dive, swim, fly, and walk; others, like the ostrich, which run, but can neither fly nor swim; and numberless kinds which can fly well, but have only slight pedestrian powers.

Man, unaided by mechanism, can, as we have seen, walk, run, swim, dive, and jump, and perform many remarkable feats; but for flying in the air he is absolutely unfitted. All his attempts (and there have been many) have up to the present been unsuccessful, whether or not he has availed himself of mechanical aids to his own bodily powers. It is said that a certain man fitted himself with apparatus in the time of James VI. of Scotland, and actually precipitated himself from the cliff below Stirling Castle, in sight of the king and his courtiers; but the apparatus collapsed, and he broke his leg, and that was the end of the experiment.

[1] M. Normand, of Havre, is building for the French Government two torpedo-boats, each having a displacement of 125 tons and 2717 effective horse-power, or 21·7 horse-power per ton of displacement. This is equivalent to 1 horse-power per 103 lbs., and is still within the limits of weight permissible for aërial flight. (See *Times*, June 19, 1893.)

But why should not man fly? It is not that he does not desire to do so. For every denizen of our precarious British climate, when he has noticed the ease with which swallows and other migratory birds fly off on the approach of winter, hundreds and even thousands of miles to the sunny south, must have wished he could do the same. One reason why we cannot fly, even with artificial aids, such as wings, is that, as in the case of the penguin or the ostrich, our bodily mechanism is specialised and our muscular power diffused in other directions, so that we could not actuate wings of sufficient area to carry us even if we had them.

M. de Lucy, a French naturalist, has shown that the wing-area of flying animals varies from about 49 square feet per lb. of weight in the gnat, and 5 square feet in the swallow, to half a square foot per lb. of weight in the Australian crane, which weighs 21 lbs. and yet flies well. If he were to adopt the last or smallest proportion, a man weighing 12 stone would require a pair of wings each of them 14 feet long by 3 feet broad, or double the area of an ordinary room door, to carry him, without taking into account the weight of the wings themselves.

In flying birds there is a strong tripod arrangement to secure firm points of attachment for the wings, and a deep keel in the breast-bone, to which the large pectoral muscles are secured. Think of the wings I have described and the absence of pivots, keel, and muscles in man, and it will be tolerably obvious why he cannot fly, even with artificial wings.

But it might be contended that a man's strength is in his legs rather than in his arms, and that it is conceivable that a successful flying-apparatus might be made if adapted for the most, instead of the least, favourable application of his bodily strength.

According to D. K. Clark ("Rules, Tables, and Data," pp. 719 and 720), a labourer working all day exerts on an average ·13 horse-power. The maximum power of a very strong man for a very short time is ·46 horse-power.

According to Dr. Haughton ("Animal Mechanics"), the oarsmen in a boat-race of 1 mile, rowed in 7 minutes, exerted each ·26 horse-power.

Suppose we take the rowing case as the maximum maintainable for, say, 7 minutes, by a man weighing 168 lbs. Then in flight he would have to sustain a weight of

$$\frac{168}{\cdot 26} = 646 \text{ lbs.}$$

per horse-power exerted, besides the weight of the apparatus.

Now, we shall find later that no birds support even half that weight per horse-power which they have the power to exert, and that recent aëroplane experiments prove its impossibility. On the ground, therefore, that he is too heavy in proportion to his strength, it is clear that man is unfitted for flight, as well as because his limbs are not adapted for it.

It does not follow, however, that by aid of mechanisms apart from his own body, and worked by power independent of his own strength, man may not imitate, compete with, and even outdo the fowls of the air.

Let us consider a few facts showing what birds can do. A gannet hovers in the air above the sea. Suddenly he nearly closes his wings, swoops down, and with a splash disappears below the surface. Shortly after he reappears with a fish in his mouth, which he swallows in a few gulps; then, after swimming on the surface a little, he reascends into the air to repeat the operation.

The swallow rises into the air with a few rapid movements of the wings, then slides down as though on an aërial switchback, and then up again till he nearly reaches his original height, or he circles round by raising one wing, like a runner rounding a curve.

The condor vulture, which measures sometimes 15 feet across the wings, will fly upwards till quite out of sight.

A flock of cranes have been seen migrating at a height of three miles, and proceeding apparently without any movement of the wings.

The peregrine falcon will swoop down upon a partridge, and, missing it by a doubling movement of the latter, will slide upwards, thus converting his kinetic into new potential energy. He will then turn and descend again, this time securing his prey.

Mr. J. E. Harting, one of the principal British ornithological authorities, has, after careful investigation, arrived at the conclusion that the speed of falcons in full flight is about 60 miles per hour. (*Field*, December 5, 1891, p. 856).
